**ABSTRACT**

Dystonia represents the third most common movement disorder in humans with over 20 genetic loci identified. TOR1A (*DYT1*), the gene responsible for the most common primary hereditary dystonia, encodes torsinA, an AAA ATPase family protein. Most cases of DYT1 dystonia are caused by a 3 bp (ΔGAG) deletion that results in the loss of a glutamic acid residue (ΔE302/303) in the carboxyl terminal region of torsinA. This torsinAΔE mutant protein has been speculated to act in a dominant-negative manner to decrease activity of wild type torsinA. *Drosophila melanogaster* has a single torsin-related gene, *dtorsin*. Null mutants of *dtorsin* exhibited locomotion defects in third instar larvae. Levels of dopamine and GTP cyclohydrolase (GTPCH) proteins were severely reduced in *dtorsin*-null brains. Further, the locomotion defect was rescued by the expression of human torsinA or feeding with dopamine.

Here, we demonstrate that human torsinAΔE dominantly inhibited locomotion in larvae and adults when expressed in neurons using a pan-neuronal promoter Elav. Dopamine and tetrahydrobiopterin (BH₄) levels were significantly reduced in larval brains and the expression level of GTPCH protein was severely impaired in adult and larval brains. When human torsinA and torsinAΔE were co-expressed in neurons in *dtorsin*-null larvae and adults, the locomotion rates and the expression levels of GTPCH protein were severely reduced. These results support the hypothesis that torsinAΔE inhibits wild type torsinA activity. Similarly, neuronal expression of a *Drosophila* DorsinΔE equivalent mutation dominantly inhibited larval locomotion and GTPCH protein expression. These results indicate that both torsinAΔE and DorsinΔE act in a dominant-negative manner. We also demonstrate that Dorsin regulates GTPCH expression at the post-transcriptional level. This *Drosophila* model of DYT1 dystonia provides an important tool for studying the differences in the molecular function between the wild type and the mutant torsin proteins.

**KEY WORDS:** Dystonia, *Drosophila*, GTP cyclohydrolase, TorsinA, Movement disorder

**INTRODUCTION**

Dystonia is the third most common movement disorder in humans, after essential tremor and Parkinson’s disease (Defazio, 2010). Dystonia comprises a group of movement disorders that are characterized by involuntary movements and abnormal postures. It is a complex disease involving at least 20 genetic loci in humans (Tarsy and Simon, 2006; Breakefield et al., 2008; Brüggemann and Klein, 2010).

One of the loci, *TOR1A/DYT1*, is responsible for most cases of early-onset dystonia and has been the most studied form of dystonia (Breakefield et al., 2001; Atai et al., 2012; Bragg et al., 2011). It is an autosomal dominant syndrome with onset between 5 to 28 years of age and low penetrance. The *TOR1A* gene encodes torsinA, a 332 amino acid protein from the AAA ATPase family. The torsinA protein is widely expressed in the body and is localized within the lumen of the endoplasmic reticulum and the nuclear envelope (Breakefield et al., 2008), but its function is still under study. A 3-bp (ΔGAG) deletion that removes one of a pair of glutamic acid residues (ΔE302/303) in the carboxyl terminal region of torsinA causes the autosomal dominant dystonia phenotype (Breakefield et al., 2008; Bragg et al., 2011). TorsinA displays LAP1 and LULL1-dependent ATPase activity, while the torsinAΔE protein is defective in this activation (Zhao et al., 2013).

The torsinAΔE (ΔE302/303) mutant protein has been speculated to act in a dominant-negative manner, so that the wild type function is reduced but not eliminated in the cells expressing both torsinA and torsinAΔE, although this has never been clearly demonstrated (Breakefield et al., 2001; Breakefield et al., 2008).

Most AAA ATPase proteins form oligomeric complexes and use energy from ATP hydrolysis to regulate protein folding, membrane trafficking, and vesicle fusion (Neuwald et al., 1999; Vale, 2000; Hanson and Whiteheart, 2005; Zhao et al., 2013).

Although torsinA is widely expressed in human tissue, it is considered to have a critical role in the central nervous system, where it is present in neurons at high levels during development and in adult life (Augood et al., 2003; Xiao et al., 2004; Vasudevan et al., 2006). In homozygous torsinA-knock-out mice, abnormal nuclear membrane morphology was observed in neurons, suggesting a functional role of torsinA in maintaining the normal structure of the nuclear envelope in the central nervous system (Goodchild et al., 2005). TorsinA has been shown to interact with nesprins, which are anchored in the outer nuclear envelope and form bridges to the cytoskeleton (Nery et al., 2008; Jungwirth et al., 2011; Atai et al., 2012), suggesting an important functional role of torsinA at the nuclear envelope, including nuclear polarization during cell migration (Nery et al., 2008). Recent studies also implicate torsinA in egress of Herpes simplex...
viruses (Maric et al., 2011) and large ribonucleoprotein particles (Jokhi et al., 2013) out from the nucleus into cytoplasm.

The fruit fly, *Drosophila melanogaster*, provides an excellent model system to study functions of human disease genes and has contributed to better understanding of many human diseases (Bellen et al., 2010). *Drosophila* has a single TOR1A-related gene, *dtorsin* (*Torsin*), at position 4C11 on the X chromosome (Ozelius et al., 1999; Breakefield et al., 2001; Wakabayashi-Ito et al., 2011). The *dtorsin*-encoded protein, Dtorsin, comprises 339 amino acids with 31.9% identity to human torsinA and also displays the characteristic features of the AAA ATPase gene family members (supplementary material Fig. S1) (Ozelius et al., 1999). We recently isolated *dtorsin*-null mutants and showed that hemizygous mutant third instar male larvae exhibited locomotion defects that were rescued by feeding dopamine (Wakabayashi-Ito et al., 2011). The *dtorsin*-null mutation was semi-lethal at the pupal stage with only less than 1% reaching adult stage. The *dtorsin* mutant exhibited a very strong genetic interaction with *Pu* (*Punch*: GTP cyclohydrolase: GTPCH), the ortholog of the human gene underlying dopa-responsive DYT5a dystonia (*GCH1*) (Segawa, 2009). Moreover, biochemical analysis revealed a severe reduction of GTPCH protein and activity in *dtorsin*-null adults and larvae, as well as marked reduction in tetrahydrobipterin (*BH4*), the terminal product of the GTPCH pathway. In contrast, levels of tyrosine hydroxylase (TH) protein, which catalyzes the rate limiting step in dopamine production, were not affected, although dopamine pools were reduced (Wakabayashi-Ito et al., 2011). Since GTPCH is rate limiting for the synthesis of *BH4*, and *BH4* is required by TH as a rate-limiting cofactor for dopamine synthesis in flies as in mammals (Krishnakumar et al., 2000), these data suggested that *dtorsin* plays a novel role in dopamine metabolism as a positive-regulator of GTPCH protein levels in *Drosophila*. Moreover, the wild type human torsinA cDNA expressed with the pan-neuronal promoter elavGAL4 rescued *dtorsin*-null male larval mobility with marked significance. These results demonstrated that the function of torsin in regulating larval locomotion is conserved between the fly and the human proteins (Wakabayashi-Ito et al., 2011). However, the fly *dtorsin*-null mutant is not an authentic DYT1 disease model system, since the *dtorsin*-null mutant line does not express any functional Dtorsin protein, while mutated torsinA protein is expressed together with normal torsinA in the DYT1 patients (Breakefield et al., 2001).

To investigate the molecular mechanism underlying the human disease caused by mutated torsinA protein using the fly system, we expressed human wild type torsinA and/or torsinAAE cDNA using the pan-neuronal GAL4 driver, elavGAL4, in fly brains. We report here that expression of the human mutant form caused larval and adult locomotion defects, and severe reduction of GTPCH protein, dopamine, and *BH4* levels in larval brains and adult heads. Moreover, expression of human torsinAAE and the wild type human torsinA in *dtorsin*-null males resulted in similar larval/adult locomotion and neurochemical defects, suggesting that the human torsinAAE exerts dominant-negative effects on human wild type torsinA protein in *Drosophila* neurons, as in human tissues. Furthermore, a comparable mutation in the *Drosophila* gene, *dtorsinAAE* also had a dominant-negative effect on larval locomotion and GTPCH protein level, as did human torsinAAE. Finally, we report that the relative amount of GTPCH RNA was similar in wild type and *dtorsin*-null adult male heads, suggesting that GTPCH protein levels depend on wild type *dtorsin*-activity at the post-transcriptional level. Our findings establish conclusively that torsinAAE dominantly inhibits the normal function of torsinA and Dtorsin including the regulation of GTPCH expression. These results demonstrate that *Drosophila* provides a powerful system for studying the molecular abnormalities caused by the torsinAAE mutation.

**RESULTS**

**Human torsinAAE dominantly inhibits larval locomotion**

In the previous study, we analyzed the peristaltic frequency of third instar larvae to quantify the difference in locomotion between wild type and mutant. The wild type third instar larvae show approximately 55 muscle contraction cycles per minute when placed on 0.7% agarose plates at room temperature. These peristaltic rates are relatively easy to monitor and provide a sensitive and reliable way of quantifying larval locomotion (Song et al., 2007; Wakabayashi-Ito et al., 2011). Males of the null mutant, *dtorsinKO13*, exhibited approximately a ~50% decrease in peristaltic rates, 22.9±2.5 (n=28, p<0.0001) (Fig. 1A, column 5), compared to wild type (55.2±2.5, n=15) (Fig. 1A, column 1). As previously observed, the wild type human torsinA cDNA expressed with the pan-neuronal driver elavGAL4 rescued *dtorsinKO13* male larval mobility to a very significant level (56.3±3.7, n=14, p<0.0001) (Fig. 1A, column 7) (Wakabayashi-Ito et al., 2011), compared to *dtorsinKO13* male larvae with the elavGAL4 transgene (27.2±1.1, n=39) (Fig. 1A, column 6). By way of controls, the pan-neuronal expression of the wild type human torsinA cDNA in wild type flies had no effect on larval mobility (54.3±2.3, n=15, p=0.7) (Fig. 1A, column 3), compared to male larvae with elavGAL4 transgene alone (53.0±1.8, n=9) (Fig. 1A, column 2). Similarly, the presence/absence of the elavGAL4 transgene had no effect on mobility in wild type (Fig. 1A, columns 1, 2) and *dtorsinKO13* larvae (Fig. 1A, columns 5, 6).

To examine the effect of mutated human torsinAAE protein in flies, we expressed human torsinAAE cDNA with the pan-neuronal elavGAL4 driver in wild type males (*w torisin*). ElavGAL4/UAS-torsinAAE males exhibited a severe locomotion deficit, approaching that of the *dtorsin*-null mutant (26.7±3.4, n=9, p<0.0001) (Fig. 1A, column 4, compared to column 2). This result demonstrates that pan-neuronal expression of human torsinAAE protein has a negative effect on larval locomotion, similar to the *dtorsin*-null state in flies, and that it interferes with the function of endogenous Dtorsin.

While pan-neuronal expression of human wild type torsinA could rescue the locomotion deficit phenotype of *dtorsinKO13* males (Fig. 1A, columns 6, 7), human torsinAAE was unable to do so (20.5±2.0, n=21) (Fig. 1A, column 8). To determine whether the human torsinAAE could inhibit wild type human torsinA, we co-expressed the human torsinAAE cDNA with the wild type human torsinA cDNA in *dtorsinKO13* male using the same elavGAL4 driver. Co-expression of human wild type torsinA and human torsinAAE resulted in a significant inhibition of mobility (25.3±2.8, n=14, p<0.0001) (Fig. 1A, column 9), compared to the rescue by human torsinA alone (Fig. 1A, column 7).

**Human torsinAAE dominantly inhibits adult locomotion**

We have also analyzed the locomotion activities in the adult stage to examine whether they were similarly affected by the neuronal expression of human torsinAAE. Adult flies, aged 3–5 days after eclosion, were placed in vials, subjected to a gentle mechanical disturbance, and then locomotion activities were quantified as the number of seconds each fly spent in motion during a 45 second
Adult male flies that were heterozygous for elavGAL4 (Drosophila melanogaster, wild-type; elavGAL4/Y) male (n = 64), p = 0.0002 (Fig. 1B, column 3), were counted for the wandering stage third instar larvae of the genotype: (1) Canton S-B (wild type) male (n = 15), (2) w/+/Y (black body, non-yellow eyes; wild type) male (n = 69), (3) w/+/Y; UAS-htorsinA/+/Y (human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; wild type) male (n = 15), (4) w/+/Y; UAS-htorsinA/+/Y; UAS-htorsinE/+/Y (human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; wild type) male (n = 15), (5) y/+; d torsinKOR13/Y (dorsin-null) male (n = 14), (6) y/+; d torsinKOR13/Y; UAS-htorsinA/+/Y (human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; wild type) male (n = 14), (7) y/+; d torsinKOR13/Y; UAS-htorsinA/+/Y; UAS-htorsinA/+/Y (human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; wild type) male (n = 14), (8) y/+; d torsinKOR13/Y; UAS-htorsinA/+/Y; UAS-htorsinA/+/Y; UAS-htorsinE/+/Y (human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; human torsinA cDNA expressed with the pan-neuronal driver elavGAL4; wild type) male (n = 14). Results are expressed as the mean ± S.E.M. ***p < 0.0001, **p < 0.001, *p < 0.05.

**Fig. 1. Neuronal expression of human torsinA/E has a dominant-negative effect on larval and adult locomotion.** (A) Peristaltic frequencies were counted for the wandering stage third instar larvae of the genotype: (1) y w/Y (wild type) male (n = 15), (2) w elavGAL4/Y (wild type) male (n = 29), (3) w elavGAL4/Y; UAS-htorsinA/+ male (n = 35), (4) w elavGAL4/Y; UAS-htorsinA/+ male (n = 35), (5) y w torsinKO13/Y (torsin-null) male (n = 39), (6) w elavGAL4 torsinKO13/Y (torsin-null) male (n = 39), (7) w elavGAL4 torsinKO13/Y; UAS-htorsinA/+ male (n = 21), (8) w elavGAL4 torsinKO13/Y; UAS-htorsinA/+ male (n = 21), (9) w elavGAL4 torsinKO13/Y; UAS-htorsinA/+ male (n = 21). The locations of GTPCH (Pu-RA: 45 kDa, Pu-RC: 43 kDa) and actin (42 kDa) are indicated. Thirty μg of proteins were loaded in each lane. (B) Adult locomotion activities were measured for the adults of the genotype: (1) Canton S-B (wild type) male (n = 47), (2) Pu222/+ (Pu null mutation) male (n = 44), (3) w elavGAL4 torsinKO13/Y (dorsin-null) male (n = 64), (4) w elavGAL4 torsinKO13/Y; UAS-htorsinA/+ male (n = 77), (5) w elavGAL4 torsinKO13/Y; UAS-htorsinE+/+ male (n = 69), (6) w elavGAL4 torsinKO13/Y; UAS-htorsinA, UAS-htorsinA/E+/+ male (n = 63). Results are expressed as the mean ± S.E.M. ***p < 0.001, **p < 0.005.

**Fig. 2. Neuronal expression of human torsinA/E has a dominant-negative effect on GTPCH protein levels in adult brains.** (A) Adult head extracts were analyzed by western blots. The membrane was probed with rabbit anti-GTPCH A/C (upper panel) and reprobed with rabbit anti-actin (lower panel). The genotypes are: (1) y w (wild type) males, (2) w elavGAL4 torsinKO13/Y (dorsin-null) males, (3) w elavGAL4 torsinKO13/Y; UAS-htorsinA+/+ males, (4) w elavGAL4 torsinKO13/Y; UAS-htorsinA/E+/+ males, (5) w elavGAL4 torsinKO13/Y; UAS-htorsinA, UAS-htorsinA/E+/+ males. The locations of GTPCH (Pu-RA: 45 kDa, Pu-RC: 43 kDa) and actin (42 kDa) are indicated. Thirty μg of proteins were loaded in each lane. (B) Adult head extracts were analyzed by western blots. The membrane was probed with rabbit anti-human torsinA and reprobed with rabbit anti-actin antibodies. The genotypes are: (1) w elavGAL4 torsinKO13/Y (dorsin-null) males, (2) w elavGAL4 torsinKO13/Y; UAS-htorsinA+/+ males, (3) w elavGAL4 torsinKO13/Y; UAS-htorsinA/E+/+ males, (4) w elavGAL4 torsinKO13/Y; UAS-htorsinA+/+ males, (5) w elavGAL4 torsinKO13/Y; UAS-htorsinA, UAS-htorsinA/E+/+ males. The locations of human torsinA (37 kDa) and actin (42 kDa) are indicated. Thirty μg of proteins were loaded in each lane.

**Human torsinA/E dominantly suppresses GTPCH expression**

We have previously shown, and confirm here, that torsinKO13 males have a severe reduction of both the 45 kDa (Pu-RA) and 43 kDa (Pu-RC) isomers of GTPCH protein in adult brains (Fig. 2A, lane 1 and 2; supplementary material Fig. S3A, columns 5, 6, 7, 8). Co-expression of the human torsinA/E with the wild type human torsinA cDNA in torsinKO13 adult male resulted in a significant reduction of locomotion activities (14.6 ± 0.9, n = 63) (Fig. 1B, column 6) compared to the rescue by human torsinA alone (Fig. 1B, column 4) (p < 0.0001). These results demonstrate that adult locomotion activities in flies are dominantly inhibited by the neuronal expression of the mutant form of human torsinA.

dtorsinKO13

adult males expressing both human torsinA and human torsinA in neurons, and compared GTPCH protein levels by western blot analysis (Fig. 2A, lanes 3–5; supplementary material Fig. S3A, columns 3–5). Pan-neuronal expression of human torsinA in dtorsinKO13

adult males, confirmed by immunoblotting using an antibody specific to human torsinA (Bragg et al., 2004) (Fig. 2B, lane 3), revealed that the mutant human torsinA protein was unable to rescue GTPCH protein levels when expressed alone in dtorsinKO13

adult males (Fig. 2A, lane 4 compared to lane 2). In contrast, neuronal expression of wild type human torsinA alone (Fig. 2B, lane 2) strongly rescued both isoforms of GTPCH in dtorsin-null males (compare Fig. 2A, lanes 2 and 3). Severe reduction of GTPCH was observed in dtorsin KO13

adult males expressing human torsinA and human torsinA together (Fig. 2A, lane 5 compared to lane 3), even though the expression of torsinA with the wild type form does not diminish the total level of human torsinA expressed in fly neurons (Fig. 2B, lane 4; supplementary material Fig. S3B).

We obtained comparable results using brain extracts from third instar larvae of the corresponding genotypes (Fig. 3; supplementary material Figs S4, S5) as those of adult head extracts (Fig. 2; supplementary material Fig. S3). That is, the htorsinAΔE transgene fails to rescue either isoform of brain GTPCH, both of which are affected by complete knockout of the dtorsin gene (Fig. 3, lane 3 and 4; supplementary material 4, columns 3, 4). Expression of wild type htorsinA (Fig. 3, lane 5; supplementary material Fig. S4, column 5) rescues expression of both isoforms (Pu-RA and Pu-RC) of GTPCH expression with Pu-RA rescue slightly more effectively than Pu-RC. The basis for this slight difference is unclear at this time. Nevertheless, these results confirm that wild type human torsinA is capable of rescuing neuronal expression of Drosophila GTPCH and demonstrate that the human torsinAΔE, when co-expressed with the wild type human transgene, dominantly suppresses GTPCH protein levels in both larval and adult brains without negatively affecting the expression of wild type human torsinA.

**Human torsinAΔE dominantly reduces BH4 and dopamine level**

Tyrosine hydroxylase is the rate limiting enzyme in dopamine synthesis (Friggi-Grelin et al., 2003) and its activity is limited by the availability of the BH4 cofactor (Kumer and Vrana, 1996). In flies and mammals, activity of GTPCH, the first enzyme in the BH4 biosynthesis pathway, controls the intracellular concentration of the cofactor (Kumer and Vrana, 1996; Krishnakumar et al., 2000; Thöny et al., 2000). Thus, dopamine pools are subject to regulation by protein levels and catalytic activity of GTPCH. We have previously reported that there is a significant reduction of GTPCH activity and dopamine levels in larval and adult head of heterozygous dtorsin KO13/+ and dtorsin KO5/+ females (Wakabayashi-Ito et al., 2011). To investigate whether expression of human torsinAΔE could also reduce the dopamine pool level, we measured BH4 levels and dopamine levels in extracts from brains of wild type male larvae expressing wild type human torsinA, dtorsin KO13 male larvae expressing human torsinAΔE, and dtorsin KO5 male larvae expressing both human torsinA and human torsinAΔE (Fig. 4A,B). The level of BH4 in dtorsin KO5 male brains was significantly lower (0.098±0.007 ng/brain, n=3 replicate samples, each sample=75 brains, p<0.001) (Fig. 4A, column 2) compared to wild type brains (0.300±0.010, n=3 replications) (Fig. 4A, column 1). The BH4 level in dtorsin KO5 male brains was significantly higher compared to those in dtorsin KO5 male brains (Fig. 4A, column 3) was significantly higher compared to those in dtorsin KO5 male brains (Fig. 4A, column 2). Neuronal expression of human torsinAΔE further decreased BH4 levels (0.018±0.002, n=3, p<0.01) (Fig. 4A, column 4 compared to column 2). Co-expression of human torsinAΔE with wild type human torsinA blocked the rescue by human torsinA (0.030±0.004, n=3, p<0.001) (Fig. 4A, column 5 compared to column 3). Similarly, the level of dopamine in dtorsin KO5 male larval brains was significantly lower (0.021±0.002 ng/brain, n=3, p<0.001) (Fig. 4B, column 2) as compared to wild type brains (0.062±0.002, n=3) (Fig. 4B, column 1). The dopamine level in dtorsin KO5 male brains expressing wild type human torsinA (0.073±0.001, n=3, p<0.001) (Fig. 4B, column 3) was significantly higher compared to that in dtorsin KO5 male brains (Fig. 4B, column 2). Neuronal expression of human torsinAΔE in dtorsin KO5 males further decreased dopamine levels (0.011±0.001, n=3, p<0.01) (Fig. 4B, column 4 compared to column 2). Co-expression of human torsinAΔE with wild type human torsinA dominantly blocked the rescue of dopamine levels by wild type torsinA (0.0074±0.0008, n=3, p<0.001) (Fig. 4B, column 5 compared to column 3).

**DtorinsE dominantly inhibits larval locomotion**

Dtorin protein has conserved amino acids E306/D307, compared to E302/E303 in human torsinA (supplementary material Fig. S1). To determine whether Dtorin with either ΔE306 or ΔD307
deleted would have a similar dominant-negative activity on the wild type Dtorin protein as observed for the human torsinA DDe302/303 mutation, we made two deletion mutant constructs of the dtorsin cDNA in E306 (UAS-dtorsinDDe) and D307 (UAS-dtorsinAD) and expressed them with the elavGAL4 driver. Although pan-neuronal expression of wild type Dtorsin did not affect larval locomotion in wild type Drosophila (peristaltic frequency 53.0±1.5, n=8, not significant) (Fig. 5, column 2) compared to wild type (53.0±1.8, n=9) (Fig. 5, column 1), wild type male larvae expressing DtorsinDDe exhibited a significant locomotion deficit (38.7±2.5, n=23, p=0.002) (Fig. 5, column 3). Male larvae co-expressing DtorsinAD and wild type Dtorsin also exhibited a locomotion deficit (38.54±2.8, n=15, p=0.0012) (Fig. 5, column 4 compared to column 1) similar to the deficit caused by expression of DtorsinDDe only (column 3).

Mutant male larvae (dorsinKO13) expressing wild type Dtorsin showed much improved larval locomotion. We tested two independent transgenic lines expressing wild type Dtorsin. Expression of a second chromosome transgene, UAS-dtorsin(B5)
Fig. 5. Neuronal expression of *Drosophila* Dtorsin\(\text{E}\) has a dominant-negative effect on larval locomotion. Peristaltic frequencies were counted for the wandering stage third instar larvae of the genotype: (1) w elavGAL4\(Y\) (wild type) male \((n=9)\), (2) w elavGAL4\(Y\); UAS-dtorsin(A11)(III)/+ male \((n=8)\), (3) w elavGAL4\(Y\); UAS-dtorsin(A12)(II)/+ male \((n=23)\), (4) w elavGAL4\(Y\); UAS-dtorsin.E(#12)(II)/+; UAS-dtorsin(A11)(III)/+ male \((n=15)\), (5) w elavGAL4 dtorsin\(\text{E}(\text{KO})\;\text{Y}\) (dtorsin-null) male \((n=48)\), (6) w elavGAL4 dtorsin\(\text{E}(\text{KO})\;\text{Y}\); UAS-dtorsin(B5)(II)/+ male \((n=20)\), (7) w elavGAL4 dtorsin\(\text{E}(\text{KO})\;\text{Y}\); UAS-dtorsin(A11)(III)/+ male \((n=23)\), (9) w elavGAL4 dtorsin\(\text{E}(\text{KO})\;\text{Y}\); UAS-dtorsin.E(#12)(II)/+ male \((n=13)\), (10) w elavGAL4 dtorsin\(\text{E}(\text{KO})\;\text{Y}\); UAS-dtorsin(A11)(III)/+; UAS-dtorsin.E(#12)(II)/+ male \((n=7)\), (12) w elavGAL4 dtorsin\(\text{E}(\text{KO})\;\text{Y}\); UAS-dtorsin(B5)(II)/+; UAS-dtorsin.E(#21)(II)/+ male \((n=14)\), (13) w elavGAL4 dtorsin\(\text{E}(\text{KO})\;\text{Y}\); UAS-dtorsin(B5)(II)/+; UAS-dtorsin.ID/+ male \((n=20)\). Results are expressed as the means ± S.E.M. **p<0.0001, *p<0.001.

in male dtorsin\(\text{KO}\)\(_3\) larvae resulted in a peristaltic frequency of 50.5±2.5, \(n=20\), p<0.0001 (Fig. 5, column 6), while expression of another transgene UAS-dtorsin(A11), on the third chromosome, rescued the peristaltic frequency to 48.2±1.1, \(n=9\), p<0.0001 (Fig. 5, column 7) compared to the dtorsin-null (dtorsin\(\text{KO}\)\(_3\)) males (Fig. 5, column 5). The presence of two copies of UAS-dtorsin transgenes (B5 and A11) together in the dtorsin-null background did not elevate locomotion further (peristaltic frequency: 50.2±1.2, \(n=23\), p<0.0001) (Fig. 5, column 8).

In striking contrast to the rescuing effect of wild type Dtorsin expression, Dtorsin\(\text{E}\) expression in male dtorsin\(\text{KO}\)\(_3\) larvae failed to rescue the locomotion deficit (22.9±2.8, \(n=13\), not significant) with a slight reduction of peristaltic rate (Fig. 5, column 9), relative to dtorsin\(\text{KO}\)\(_3\) males (Fig. 5, column 5). Similarly, mutant males co-expressing Dtorsin\(\text{E}\) and wild type Dtorsin transgenes exhibited a locomotion deficit that was not significantly different from that of the dtorsin\(\text{KO}\)\(_3\) larvae (UAS-dtorsin(A11) and UAS-dtorsin(\#12); 32.4±4.2, \(n=7\), not significant) (Fig. 5, column 11); UAS-dtorsin(B5) and UAS-dtorsin(\#21): 29.9±3.6, \(n=14\), not significant) (Fig. 5, column 12).

Interestingly, pan-neuronal expression of Dtorsin\(\text{D}\) in dtorsin\(\text{KO}\)\(_3\) males rescued the larval mobility (45.2±2.9, \(n=11\), p<0.0001) (Fig. 5, column 10 compared to column 5). Similarly, co-expression of Dtorsin\(\text{D}\) with the wild type Dtorsin in dtorsin\(\text{KO}\)\(_3\) males had no effect on locomotion (peristaltic frequency: 49.4±3.2, \(n=20\)) (Fig. 5, column 13). These results indicate that E302/303 of human torsinA protein and E306 of *Drosophila* Dtorsin protein are functionally similar and that deletion of these glutamates both cause reduced locomotion in *Drosophila* larvae, presumably due to the same functional abnormality, while Dtorsin\(\text{D}\) appears similar to wild type Dtorsin.

**Dtorsin\(\text{E}\) dominantly suppresses GTPCH expression**

These studies described above demonstrate a striking similarity in the dominant inhibition of larval locomotion by Dtorsin\(\text{D}\) and human torsin\(\text{D}\). Since we found that human torsin\(\text{A}\) dominantly inhibited GTPCH protein expression, we next examined the protein levels of GTPCH in adult male heads expressing wild type Dtorsin and Dtorsin\(\text{D}\) in the dtorsin-null background (Fig. 6). The expression of endogenous GTPCH in the dtorsin\(\text{KO}\)\(_3\) mutant line and in the dtorsin\(\text{KO}\)\(_3\) elavGAL4 transgene line revealed similar patterns of reduced GTPCH expression of both RA and RC isoforms (Fig. 6, lane 2 and 3). Dtorsin\(\text{D}\) expressed in dtorsin\(\text{KO}\)\(_3\) males, under the control of elavGAL4, rescued GTPCH expression substantially (Fig. 6, lane 4, compared to lane 3; supplementary material Fig. S6, column 4, compared to column 3).

Dtorsin\(\text{D}\) expressed in dtorsin\(\text{KO}\)\(_3\) neurons failed to affect the GTPCH protein level (Fig. 6, lane 5, compared to lane 3; supplementary material Fig. S6, column 5, compared to column 3). Severe reduction of GTPCH was also observed in adult males co-expressing Dtorsin and Dtorsin\(\text{D}\) in dtorsin\(\text{KO}\)\(_3\) (Fig. 6, lane
Fig. 6. Neuronal expression of Drosophila Dtorsin\AE has a dominant-negative effect on GTPCH protein levels. Adult head extracts were analyzed by western blots. The membrane was probed with rabbit anti-GTPCH A/C (upper panel) and reprobed with rabbit anti-actin (lower panel). The genotypes are: (1) y w\(^{Y}\) (wild type) males, (2) y w\(^{dorsin\text{KO}13\text{Y}}\) (dorsin-null) males, (3) w\(^{elav\text{GAL}4\;dorsin\text{KO}13\text{Y}}\) (dorsin-null) males, (4) w\(^{elav\text{GAL}4\;dorsin\text{KO}13\text{Y}}\) UAS-dtorsin\(^{\text{B5}[\text{III}]\text{+}}\) males, (5) w\(^{elav\text{GAL}4\;dorsin\text{KO}13\text{Y}}\) UAS-dtorsin\(^{\text{E}[\text{#12}[\text{III}]\text{+}}\) males, (6) w\(^{elav\text{GAL}4\;dorsin\text{KO}13\text{Y}}\) UAS-dtorsin\(^{\text{E}[\text{#12}[\text{III}]\text{+}}\) males. The locations of GTPCH (Pu-RA: 45 kDa, Pu-RC: 43 kDa) and actin (42 kDa) are indicated. Thirty \(\mu\)g of proteins were loaded in each lane.

The mobility defect of larvae expressing either human torsin\AE or Dtorsin\AE can be rescued by dopamine supplementation

In Drosophila, ingestion of dopamine increases dopamine pools in the fly head, though in mammals peripheral dopamine does not enter the brain (Chaudhuri et al., 2007). We previously showed that the locomotor deficit phenotype in \(dorsin^{\text{KO13}}\) mutant male was partially rescued by dopamine supplementation to the larval growth medium, but not by serotonin or octopamine (Wakabayashi-Ito et al., 2011). Since we observed in the current study a very similar reduction of dopamine levels in larval brains expressing human torsin\AE, we hypothesized that dopamine supplementation to the larval growth medium could also restore the locomotion defect of larvae expressing human torsin\AE (or Drosophila Dtorsin\AE). To test this hypothesis, we added 20 nM dopamine in the food of larvae with different \(dorsin\) genotypes (Fig. 4C). Dopamine supplementation had no effect on the locomotion of wild type (\(elav\text{GAL4}/\text{Y}\) larvae (56.3±1.0, n=11, p=0.562) (Fig. 4C, column 2) compared to the larvae of the wild type without dopamine (55.4±1.0, n=12) (Fig. 4C, column 1). In contrast, dopamine supplementation substantially rescued the locomotion defect of \(dorsin^{\text{KO13}}\) larvae (49.3±1.8, n=11, p<0.0001) (Fig. 4C, column 4) compared to the larvae of the same genotype without dopamine (27.7±2.8, n=11) (Fig. 4C, column 3) confirming our previous results (Wakabayashi-Ito et al., 2011). Dopamine supplementation also rescued the locomotion defect of \(dorsin^{\text{KO13}}\) larvae expressing Dorsin\AE and wild type Dorsin (51.4±2.6, n=8, p<0.0001) (Fig. 4C, column 6) compared to the larvae of the same genotype without dopamine (25.9±2.5, n=11) (Fig. 4C, column 5). Similarly, dopamine supplementation also substantially rescued the locomotion defect of \(dorsin^{\text{KO13}}\) larvae expressing human torsin\AE and wild type torsin\(\text{A}\) (52.2±3.6, n=5, p<0.0001) (Fig. 4C, column 8) compared to the larvae of the same genotype without dopamine (25.3±2.8, n=14) (Fig. 4C, column 7). These results demonstrate that locomotor defects caused by the pan-neuronal expression of human torsin\AE or Dtorsin\AE, measured by our larval locomotion assay, can be substantially rescued by dopamine supplementation. As a control, knockdown of GTPCH (\(Pu\)) mRNA expression levels was accomplished by neuronal expression of GTPCH RNAi, a short-hairpin specific for GTPCH (\(Pu\)) gene (Fig. 7), which was accompanied by a moderate reduction of larval locomotion (38.7±1.1, n=11) (Fig. 4C, column 9). Dopamine supplementation almost completely rescued locomotion defect of wild type larvae expressing GTPCH RNAi (57.5±1.0, n=10, p<0.0001) (Fig. 4C, column 10). Dopamine supplementation also substantially rescued the locomotion defect of \(dorsin^{\text{KO13}}\) larvae expressing GTPCH RNAi (42.3±1.7, n=10, p<0.0001) (Fig. 4C, column 12) compared to the larvae of the same genotype without dopamine (24.4±3.1, n=11) (Fig. 4C, column 11).

**The expression level of GTPCH is regulated at the post-transcriptional level**

Having found that Dorsin/torsin\(\text{A}\) regulates GTPCH protein, we next tested whether torsin regulates GTPCH expression at the transcriptional or post-transcriptional level. In order to analyze these alternative possibilities, we prepared total RNA from adult brains and analyzed GTPCH (\(Pu\)) mRNA levels by quantitative RT-PCR (qRT-PCR). The relative amount of GTPCH mRNA was determined by normalizing to mRNA for the housekeeping gene \(Rpl32\) (\(rp49\)) as an internal control (see Materials and Methods). A significant increase, rather than reduction of GTPCH mRNA levels was observed in the brains of \(elav\text{GAL4} /dorsin^{\text{KO13}[\text{Y}]}; Y\) (4.52±0.20, n=3, p<0.0001) (Fig. 7, column 2) compared to those in wild type: \(elav\text{GAL4}/\text{Y}\) (1.00, n=3) (Fig. 7, column 1). Expression of wild type human torsin\(\text{A}\) (2.57±0.24, n=3,

Fig. 7. Drosophila dtorsin-null mutation does not reduce GTPCH mRNA levels. Total RNA was extracted from adult heads. Relative amount of GTPCH RNA was calculated compared to the internal control, \(Rpl32\) (\(rp49\)) RNA in each sample. The genotypes are: (1) \(w^{elav\text{GAL4}/\text{Y}}\) males (n=3), (2) \(w^{elav\text{GAL4} /dorsin^{\text{KO13}[\text{Y}]}}\) (dorsin-null) males (n=3), (3) \(w^{elav\text{GAL4}/\text{Y}}\); UAS-\text{htr}\(^{\text{A}+}\) males (n=3), (4) \(w^{elav\text{GAL4}/\text{Y}}\); UAS-\text{htr}\(^{\text{A}+}\) males (n=3), and (5) \(w^{elav\text{GAL4}/\text{Y}}\); GTPCH (\(Pu\))-RNAi (v107296) males (n=3). Results are expressed as the means±S.E.M. ***p<0.0001, **p<0.001.
defect, or the depletion of GTPCH protein, BH4, and dopamine (Figs 1, 5) (Wakabayashi-Ito et al., 2011). Pan-neuronal expression suppresses the wild type protein activity (Breakefield et al., 2001). These results strongly support the reduction of GTPCH protein levels results in a shortage of BH4 (O’Donnell et al., 1989; Thony et al., 2000). Severe Drosophila (Wakabayashi-Ito et al., 2011). The pan-neuronal expression of dopamine depletion since TH protein is unaffected in the mutant null animals, suggesting GTPCH deficiency is responsible for 31.9% amino acid identity to human torsinA (supplementary DISCUSSION Drosophila has a single torsin-related gene, dtorsin (Torsin), with 31.9% amino acid identity to human torsinA (supplementary material Fig. S1). dtorsin-null animals have reduced locomotion at the third instar larval stage and reduced pigmentation in the adult stage (Wakabayashi-Ito et al., 2011). The dopamine levels and GTPCH activity/protein levels are severely reduced in dtorsin-null animals, suggesting GTPCH deficiency is responsible for dopamine depletion since TH protein is unaffected in the mutant (Wakabayashi-Ito et al., 2011). The pan-neuronal expression of wild type Drosophila Dtorsin or human torsinA rescued the locomotion defect in dtorsin-null larvae and adults, suggesting that human torsinA and Drosophila Dtorsin are functionally conserved (Figs 1, 5) (Wakabayashi-Ito et al., 2011). Pan-neuronal expression of human torsinAΔE protein alone did not rescue the locomotion defect, or the depletion of GTPCH protein, BH4, and dopamine (Figs 1–4) in dtorsin-null larvae and adults, demonstrating that human torsinAΔE protein is inactive. Further, co-expression of human wild type torsinA and torsinAΔE did not rescue the defects (Figs 1–4), demonstrating a dominant-negative effect of torsinAΔE on wild type torsinA activity. These results, for the first time, clearly show that torsinAΔE inhibits wild type torsinA activity in neurons, resulting in reduced locomotion and dopamine levels in Drosophila. Drosophila Dtorsin has similar types of amino acids E306-D307 compared to human torsinA E302-E303 in the conserved location near the C terminal region of the protein (supplementary material Fig. S1). DtorsinΔE306, when expressed in neurons, had a similar dominant-negative effect on locomotion and GTPCH protein levels as human torsinAΔE (Figs 5, 6), while DtorsinAD307 was still active as it could rescue the dtorsin-null locomotion defect as well as GTPCH protein expression, and had no inhibitory effect on wild type Dtorsin (Fig. 5; supplementary material Fig. S7). Furthermore, neuronal expression of DtorsinΔE306 inhibited locomotion of wild type larvae, demonstrating a dominant-negative effect on the wild type protein. The phenotypes caused by neuronal expression of human torsinAΔE or Drosophila DtorsinAΔE are indistinguishable from those of dtorsin-null larvae or adults, resulting in co-reduction of locomotion, dopamine levels, and GTPCH protein levels. These results strongly support the hypothesis that torsinAΔE acts as a dominant-negative molecule that suppresses the wild type protein activity (Breakefield et al, 2001).

We have demonstrated that dtorsin-null larvae and DtorsinAΔE (or human torsinAΔE) expressing larvae have very similar phenotypes, resulting in the severely decreased level of GTPCH. Rates of dopamine synthesis depend on the activity of TH, which in turn depends on the amount of BH4 produced by GTPCH (O’Donnell et al., 1989; Thony et al., 2000). Severe reduction of GTPCH protein levels results in a shortage of BH4 and decreased activity of TH, thereby leading to decreased dopamine pool levels in brains of dtorsin-null animals (Wakabayashi-Ito et al., 2011), as well as in brains expressing torsinAΔE (Fig. 4A,B). This defect, however, is unlikely to be the only defect in the dopamine signal transduction system in dtorsin-null or torsinAΔE-expressing animals. Although feeding dopamine could partially rescue the locomotion defect in our assay in dtorsin-null larvae (Wakabayashi-Ito et al., 2011) or in DtorsinAΔE (or human torsinAΔE)-expressing larvae (Fig. 4C), very few larvae of dtorsin-null or torsinAΔE-expressing animals survived until the late third instar larval stage (data not shown). Early lethality could be the result of earlier developmental requirements for dopamine since strong loss-of-function mutations in the TH-encoding gene cause embryonic lethality in Drosophila (Neckameyer and White, 1993). Alternatively, Dtorsin may be affecting other neurotransmitter signaling systems directly or indirectly through dysfunction in dopaminergic circuitry. In the case of DYT1 dystonia patients, L-dopa is not therapeutic, suggesting that dopamine cannot compensate for defects resulting from mutant torsinA (Breakefield et al., 2008). Recent publications in mouse DYT1 model systems demonstrated defective dopamine D2 receptor signaling in the striatal cholinergic neurons (Sciamanna et al., 2009; Sciamanna et al., 2011; Sciamanna et al., 2012). The lack of responsiveness of DYT1 patients to L-dopa treatment would be expected if the dopamine D2 receptor signaling or other component of the dopaminergic system is defective in addition to defects in dopamine synthesis.

Translational control of localized mRNA is a common mechanism for regulating protein expression in specific subdomains of a cell, in processes such as body axis formation, asymmetric cell division and synaptic plasticity (St Johnston, 2005; Holt and Bullock, 2009; Medioni et al., 2012). These localized mRNAs are often transported in large ribonucleoprotein particles (RNPs) or RNA granules (Kiebler and DesGroseillers, 2000; Kiebler and Bassell, 2006; Holt and Bullock, 2009; Medioni et al., 2012). We have recently shown that dtorsin is involved in export of large RNPs out of nuclei on the way to the neuromuscular junction (Jokhi et al., 2013). Here, we have shown that the mRNA levels of GTPCH/Punch gene were not significantly decreased in dtorsin-null adult brains (Fig. 7), suggesting that the regulation of GTPCH/Punch expression is at the post-transcriptional level. This is consistent with a model in which GTPCH mRNA is transported through the nuclear membrane as a part of a large RNP complex whose transport depends on Dtorsin. If this hypothesis is correct, the Dtorsin protein could regulate the nuclear export and subsequent transport of large RNP complexes with subsequent compromise of the translation of the GTPCH mRNA. This nuclear export of mRNAs within RNPs could explain the mechanism by which torsin regulates expression of multiple proteins such as GTPCH and dopamine D2 receptor at the same time and thereby modulate synaptic plasticity (Sciamanna et al., 2012). Further testing of this hypothesis will be very important for understanding the molecular function of torsin proteins and the pathophysiology of DYT1 disease in human patients. The Drosophila system with its abundant genetic tools provides us an excellent model system to probe this hypothesis.

MATERIALS AND METHODS Fly stocks Flies were grown on standard medium containing cornmeal, yeast and agar at 25°C in fly incubators with a constant humidity of 70%
(Ashburner and Roote, 2007). ElevGAL4 transgenic strain was obtained from the Drosophila Stock Center (Bloomington, IN USA). The datorsin null lines, y w datorsinKO10Fm7i, Act-GFP and y w ElevGAL4 datorsinKO10j Fm7i, Act-GFP were described previously (Wakabayashi-Ito et al., 2011). The Punch-null line, Puz22, was previously described (Mackay et al., 1985). The RNAi line for GTPCH (Pu) gene, v107296 (KK107763) (Dietzl et al., 2007), was obtained from Vienna Drosophila RNAi Stock Center (Vienna, Austria). This RNAi line has 514 nt hairpin sequences that target all three isoforms (Pu-RA, Pu-RB, and Pu-RC) of GTPCH isoform A/C transcripts.

**UAS lines**

datorsinAE and datorsinAD cDNA constructs were made from the wild type datorsin cDNA using QuikChange II XL Site-Directed Mutagenesis kit (Agilent Technologies, Santa Clara, CA USA). Briefly, a 1.2 kb wild type datorsin cDNA was cut from pUAST-datorsin with EcoRI and NotI (Wakabayashi-Ito et al., 2011) and cloned between the EcoRI and NotI sites of pBluescript II KS (Agilent Technologies). Mutagenesis strand synthesis was done following the manufacturer’s protocol using two primers torp4aE3 (5’-CTAAATGAGAATTTAATATGTCAATGATT-3’ and torp4aE5 (5’-GCGAACAACAAAAAATCTTGGCATTATTTATTTTGTTCCGC-3’) to make datorsin cDNA that lacks GAC (D307), respectively. After confirming mutated sequences, the insert was again cut out with EcoRI and NotI and inserted between EcoRI and NotI sites of pUAST to produce pUAST-datorsinAE and pUAST-datorsinAD. The transgenic lines E12 (pUAST-datorsinAE transgene on the second chromosome), E21 (pUAST-datorsinAD on the third chromosome) and D19 (pUAST-datorsin AD on the third chromosome) were used for the experiments.

A 1.0 kb human torsinAe cDNA was amplified from pCDNA3-htorM (Hewett et al., 2000) by PCR using the following primers htor5 (5’-GCGGATATCCCATGAACTGCGCCGCGCTGCAGG-3’) and htor3 (5’-CTCGAGACGCGCCTAACATCTGAGTGAA-3’). The PCR product was digested with Acc65I and NotI and inserted between Acc65I and NotI sites of pUAST. Injections were performed by Genetic Services, Inc. (Cambridge, MA USA). The transgenic line #24 with UASh-torsinAeAE transgene on the second chromosome was used for the experiments.

**Larval locomotion assay**

The larval locomotion assay was done as described previously (Wakabayashi-Ito et al., 2011). Briefly, a wandering third instar larva of a particular genotype was individually picked from the vial with a bamboo stick and placed at the center of a 100 mm petri dish containing 0.7% agarose at room temperature placed on a light box. Larval locomotion was recorded for one minute using a Canon Powershot G7 digital camera attached to a stereoscopic microscope. Peristaltic frequency was counted manually using the Quicktime movie. The experiments were done in a double-blinded manner with only numbers assigned for each genotype. Peristaltic rates are usually highly reproducible with little variation for each genotype with relatively small SEM values. Since we were unable to get reproducible with little variation for each genotype with relatively small SEM values. Since we were unable to get reproducible with little variation for each genotype with relatively small SEM values.

**Adult locomotion assay**

The adult locomotion assay was adapted from the method described previously (Carbone et al., 2006). Flies were maintained at 25°C and a 12 hour light–12 hour dark circadian cycle. At least 10 males of each genotype, aged 3–5 days post-eclosion, were assayed in a double-blind manner. Individual flies were placed in vials and allowed to acclimate to the vial for 1 hour prior to assay. The vials were subjected to a gentle mechanical disturbance, and then locomotion behavior was quantified as the number of seconds each fly spent in motion during a 45 second period. The experiments were done in a double-blinded manner with only numbers assigned for each genotype. Each assay was replicated five times per fly. All assays were completed at the same time of the day (12 pm–3 pm). The results are usually highly reproducible with little variation with relatively small SEM values.

**HPLC analysis**

Dopamine and BH4 were separated by HPLC using a CoulArray HPLC system (model 5600A; ESA, Chelmsford, MA USA) and a Synergi 4μm Hydro-RP column (4.6x150 mm; Phenomenex, Torrance, CA), as described (Chaudhuri et al., 2007). Brains of third instar larvae or heads of 48–72 hour post-emergence adult flies were homogenized in 0.1 M perchloric acid. One hundred third instar larval brains or 75 to 200 adult heads were extracted in 100–200 μl of 0.1 M perchloric acid. Ten microliters of each extract were injected for each sample. Pool sizes were determined relative to freshly prepared standards (Sigma-Aldrich, St. Louis, MO USA). Analysis was performed using ESA CoulArray software.

**Western blot analysis**

Detection of proteins in adult heads (Figs 2, 6; supplementary material Figs S3, S6, S7) was performed, as described (Wakabayashi-Ito et al., 2011). Briefly, fifty heads from adult males of each genotype were homogenized in 100 μl RIPA buffer [50 mM Tris-HCl, pH 8.0, 150 mM NaCl, 1% NP40, 0.5% deoxycholate, 0.1% SDS (sodium dodecyl sulfate)] with Protein Inhibitor Cocktail (Roche Applied Science, Indianapolis, IN USA). The proteins (30 μg), which corresponded to approximately three adult heads, were separated by electrophoresis in 10% SDS-polyacrylamide gels and transferred to Protran BA85 (0.45 μm pore size) nitrocellulose membranes (Sigma-Aldrich). Membranes were blocked with 10% non-fat dry milk in TBST (20 mM Tris-HCl buffer, pH 7.6, 167 mM sodium chloride, 0.1% Tween 20) and incubated with antibodies in 5% non-fat dry milk in TBST. GTPCH protein was detected using affinity-purified polyclonal anti-GTPCH isoform A/C antibody (Chen et al., 1994) at 1:50,000 dilution. Human torsinA protein was detected using rabbit polyclonal anti-human torsinA TA-2 (Bragg et al., 2004) at 1:5000 dilution, Rabbit anti-actin antibody (Sigma-Aldrich) was used at 1:5000 dilution. The secondary antibody was used was peroxidase-conjugated anti-rabbit IgG at 1:5000 dilution (Jackson ImmunoResearch, West Grove, PA USA). Signals were detected using Supersignal West Pico Chemiluminescent Substrate (Thermo Fisher Scientific, Waltham, MA USA).

For detection of proteins in larval brains (Fig. 3; supplementary material Figs S4, S5), fifteen whole male brains from each genotype were dissected from late third instar larvae in phosphate-buffered saline (PBS) and homogenized in 50 μl of RIPA lysis buffer (AMRESCO)2 mM DTT/1× protease inhibitor cocktail (AMRESCO, Solon, OH USA) containing 2 mM EDTA added immediately before use. Forty μl of supernatant were mixed with 14.9 μl of NuPage LDS sample buffer (Life Technologies, Carlsbad, CA USA) and 5.7 μl of 500 mM DTT. Twenty μg of proteins per lane were separated by electrophoresis on 4–12% NuPage Bis-Tris mini gels (Life Technologies). Separated proteins were transferred into a nitrocellulose membrane, and blocked with 2.5% BSA in TBST. Rabbit anti-GTPCH isoform A/C was used at 1:8000, while mouse anti-syntaxin (8C3 supernatant, Developmental Studies Hybridoma Bank) (1:200) was used in 5% BSA in TBST. Horseradish peroxidase-conjugated anti-rabbit (1:20,000) and anti-mouse (1:20,000) IgG secondary antibodies (VWR International, Randor, CA USA) were used in 2.5% BSA in TBST.

After the reaction with the peroxidase substrate, the membranes were exposed with multiple exposure times and the optimal condition for densitometry measurement was determined. Relative densities of GTPCH bands (two major species, RA and RC, were combined) and human torsinA bands were quantified from scanned images of X-ray films by the NIH ImageJ 1.40 g software (‘‘gels’’ function under ‘‘analyze’’ command; http://rsb.info.nih.gov/ij/docs/guide/14-30.html#sec: Analyze-Menu) using densities of actin bands or syntaxin bands as internal standards.
Isolation of RNA
Total RNA was extracted from thirty adult male fly heads suspended in 100 µl PBS/0.1% Triton X-100 using 800 µl TRI reagent (Molecular Research Center, Inc., Cincinnati, OH USA) and 80 µl of BCP (Molecular Research Center, Inc.) following the manufacturer’s protocol.

qRT-PCR analysis
qRT-PCR was performed as described previously with minor modifications (Balaj et al., 2011). Total RNA (2 µg) was converted into cDNA with the Omniscript reverse transcription kit (Qiagen, Valencia, CA USA) using random primers, according to manufacturer’s recommendations, and a 1:10 fraction (corresponding to 2.5 ng reverse transcribed RNA) was used for qRT-PCR. All reactions were performed in a 20 µl reaction using Power SYBR Green PCR Master Mix (Life Technologies) and 320 nM of each primer. Amplification conditions consisted of: 1 cycle of 50°C; 2 minutes; 1 cycle of 95°C, 10 minutes; 40 cycles of 95°C, 15 seconds; and 60°C, 1 minute followed by a dissociation curve analysis of each amplicon on the 7000 ABI Prism system (Life Technologies). Ct values were analyzed in auto mode. The Ct-values were normalized to the housekeeping gene RpL32 (rp49) in each sample (Brown et al., 2009; Willis et al., 2010). The following primers were used for qRT-PCR: RpL32: F: 5'-CCCAAAGGTTACGCAGAACAG-3'; R: 5'-GTTCGATCCGTAACCGATGT-3'; Psa: F: 5'-CGGA TAGTGATGGCCACGAG-3'; R: 5'-AGTAGACGATACGGAGTTGCG-3'.

Fig. S3. Neuronal expression of human torsinA\(\Delta E\) has a dominant-negative effect on GTPCH protein levels in adult brains. (A) Adult head extracts were analyzed by western blots. The membrane was probed with rabbit anti-GTPCH A/C and reprobed with rabbit anti-actin. The relative densities of combined two human torsinA bands are calculated as syntaxin bands as internal standards as shown here. The genotypes are: (1) \(\text{PuZ22}^{+/+}\) (\(\text{Pu}\) null mutation) males, (2) Canton S-B (wild type) males, (3) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\) males, (4) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA/}\Delta\text{E}^{+/+}\) males, (5) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA/}\Delta\text{E}^{+/+}\) males. ***\(p < 0.0001\).

(B) Adult head extracts were analyzed by western blots. The membrane was probed with rabbit anti-human torsinA and rabbit anti-actin antibodies. The relative densities of combined two human torsinA bands are calculated using actin bands as internal standards as shown here. The genotypes are: (1) \(\text{PuZ22}^{+/+}\) (\(\text{Pu}\) null mutation) males, (2) Canton S-B (wild type) males, (3) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\) males, (4) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA/}\Delta\text{E}^{+/+}\) males, (5) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA/}\Delta\text{E}^{+/+}\) males. ***\(p < 0.0001\).

Fig. S4. Neuronal expression of human torsinA\(\Delta E\) has a dominant-negative effect on GTPCH protein levels in larval brains. Larval brain extracts were analyzed by western blots. The membrane was probed with rabbit anti-GTPCH A/C and reprobed with mouse anti-syntaxin. The relative densities of combined two human torsinA bands are calculated as syntaxin bands as internal standards as shown here. The genotypes are: (1) \(\text{PuZ22}^{+/+}\) (\(\text{Pu}\) null mutation) males, (2) Canton S-B (wild type) males, (3) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\) (\(\text{dtorsin-null}\) males, (4) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA/}\Delta\text{E}^{+/+}\) males, (5) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA/}\Delta\text{E}^{+/+}\) males, (6) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA, UAS-htorsinA/}\Delta\text{E}^{+/+}\) males. ***\(p < 0.0001\).

Fig. S5. Expression of human torsinA protein in larval brains driven by the pan-neuronal elavGAL4. (A) Larval brain extracts were analyzed by western blots. The membrane was probed with rabbit anti-human torsinA and mouse anti-syntaxin antibodies. The genotypes are: (1) \(\text{PuZ22}^{+/+}\) (\(\text{Pu}\) null mutation) males, (2) Canton S-B (wild type) males, (3) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\) (\(\text{dtorsin-null}\) males, (4) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA/}\Delta\text{E}^{+/+}\) males, (5) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA/}\Delta\text{E}^{+/+}\) males, (6) \(\text{w elavGAL4 dtorsinKO13}^{+/+}\;\text{UAS-htorsinA, UAS-htorsinA/}\Delta\text{E}^{+/+}\) males. The locations of human torsinA and are indicated. Twenty \(\mu\)g of proteins were loaded in each lane.
Fig. S6. Neuronal expression of *Drosophila* DtorsinΔE has a dominant-negative effect on GTPCH protein levels in adult brains. Adult head extracts were analyzed by western blots. The membrane was probed with rabbit anti-GTPCH A/C and reprobed with rabbit anti-actin. The relative densities of combined GTPCH bands (RA and RC) are calculated as actin bands as internal standards as shown here. The genotypes are: (1) *yw/Y* (wild type) males (*n* = 3), (2) *yw dtorsinKO13/Y* (dtorsin-null) males (*n* = 3), (3) *elavGAL4 dtorsinKO13/Y* (dtorsin-null) males (*n* = 3), (4) *elavGAL4 dtorsinKO13/Y; UAS-dtorsin/B5(II)+* males (*n* = 3), (5) *elavGAL4 dtorsinKO13/Y; UAS-dtorsin.B5(III)+* males (*n* = 3), (6) *elavGAL4 dtorsinKO13/Y; UAS-dtorsin.B5(II)+* males (*n* = 3). ***p < 0.001.

Fig. S7. Neuronal expression of *Drosophila* DtorsinΔD substantially rescues GTPCH protein levels in adult brains. (A) Adult head extracts were analyzed by western blots. The membrane was probed with rabbit anti-GTPCH A/C (upper panel) and reprobed with rabbit anti-actin (lower panel). The genotypes are: (1) *yw/Y* (wild type) males, (2) *elavGAL4 dtorsinKO13/Y* (dtorsin-null) males, (3) *elavGAL4 dtorsinKO13/Y; UAS- dtorsinΔE+* males, (4) *elavGAL4 dtorsinKO13/Y; UAS- dtorsinΔD+* males, (5) *elavGAL4 dtorsinKO13/Y; UAS-dtorsin.B5(II)+* males. The locations of GTPCH (Pu-RA: 45 kDa, Pu-RC: 43 kDa) and actin (42 kDa) are indicated. Thirty μg of proteins were loaded in each lane. (B) The relative densities of combined GTPCH bands (RA and RC) are calculated as actin bands as internal standards as shown here. The genotypes are the same as in panel A of this figure.
