**ABSTRACT**

The origin of somatic cell lineages during testicular development is controversial in mammals. Employing basal amphibian tetrapod *Xenopus tropicalis* we established a cell culture derived from testes of juvenile male. Expression analysis showed transcription of some pluripotency genes and Sertoli cell, peritubular myoid cell and mesenchymal cell markers. Transcription of germine-specific genes was downregulated. Immunocytochemistry revealed that a majority of cells express vimentin and co-express Sox9 and smooth muscle α-actin (Sma), indicating the existence of a common progenitor of Sertoli and peritubular myoid cell lineages. Microinjection of transgenic, red fluorescent protein (RFP)-positive somatic testicular cells into the peritoneal cavity of *X. tropicalis* tadpoles resulted in cell deposits in heart, pronephros and intestine, and later in a strong proliferation and formation of cell-to-cell net growing through the tadpole body. Immunohistochemistry analysis of transplanted tadpoles showed a strong expression of vimentin in RFP-positive cells. No co-localization of Sox9 and Sma signals was observed during the first three weeks indicating their dedifferentiation to migratory-active mesenchymal cells recently described in human testicular biopsies.

**KEY WORDS:** Testicular somatic cells, *Xenopus tropicalis*, Migration potential, Common progenitor

**INTRODUCTION**

The architecture of seminiferous tubules is tightly associated with the presence of peritubular myoid cells (PTMC) and Sertoli cells (SC) both forming basement membranes underlying the seminiferous epithelium (Skinner et al., 1985). Sertoli cells (SC) are also indispensable for germ cell maturation and differentiation (Berndtson and Thompson, 1990; Johnson et al., 1984). They stretch to the lumen and have an intimate contact with developing gametes ranging from spermatogonia located on the base to spermatids in the centre. Sertoli cells also provide a signalling niche via expression of several growth factors and cytokines (De Rooij, 2009). In addition, with PTMCs they participate in the formation of seminiferous cords and appropriate vascularization through the expression of Sry (Koopman et al., 1990) and downstream signalling cascades (Bott et al., 2006). Moreover, they function as an immunological barrier since testes are an immunologically privileged organ (Dufour et al., 2005). Leydig cells start to differentiate in the end of the proliferative phase of Sertoli cells (Baker et al., 1999; Nef et al., 2000; O’Shaughnessy et al., 2008) and form the stable cell line indispensable for the production of male sex hormones.

The origin of individual testicular somatic cell lineages in mouse is still controversial. Precursors of Sertoli cells were detected in the population of coelomic epithelial cells migrated into the gonad 11.5 days post-coitum (Karl and Capel, 1998). Later publications disproved these findings and showed that pre-Sertoli cells are already present in the developing gonad together with arrived germ cells and form Sertoli germ cell mass (SGCM) (reviewed in Cool et al., 2012). Based on the expression of the low affinity neurotrophin receptor p75, peritubular myoid cells were found as mesenchymal precursors migrated from an adjacent mesonephric tissue (Campagnolo et al., 2001); however, this result was also disproved and only endothelial cells, but not PTMCs, were identified as a migrating population from mesonephros to the gonadal base (Combes et al., 2009). Authors performed *ex vivo* assay in which they co-cultured a wild-type male genital ridge alongside mesonephroi constitutively expressing GFP (Nishino et al., 2000). They found that endothelial cells with VE-cadherin expression, and not p75 positive PTMCs, are the only migrating cells entering the gonad. Furthermore, endothelial cells were identified as being indispensable for establishing a proper seminiferous tubule architecture (Combes et al., 2009).

Regarding humans, Chikhovskaya et al. (2012) used frozen testicular biopsies for variable enzymatic digestions and subsequent cultivation *in vitro*. Over 30-50 days embryonic stem cell (ESC)-like colonies emerged. Gene expression analysis revealed a low level of pluripotency markers such as *POU5F1, NANOG* and *SOX2* which was in disagreement with similar studies performed on mouse where such colonies were found to be derived from dedifferentiated spermatogonial stem cells (SSCs) and showed the ability to form teratoma (Guan et al., 2006; Kanatsu-Shinohara et al., 2004, 2008; Ko et al., 2009). Human testicular cells expressed mesenchymal stem cell (MSC) markers and were able to differentiate to three mesodermal lineages (adipocytes, chondrocytes and osteocytes) indicating their multipotent but not pluripotent character (Chikhovskaya et al., 2014).

So far the majority of experiments employing testicular cells have been conducted in mammalian models; however, studies of their migration and differentiation potential *in vivo* via transplantation into early embryos are hampered by the inner embryonic development in the womb. In addition, Sertoli cells are able to survive after xenogeneic transplantation into the evolutionarily distant host. This feature is interesting for basic research in the field through the expression of Sry (Koopman et al., 1990) and downstream signalling cascades (Bott et al., 2006). Moreover, they function as an immunological barrier since testes are an immunologically privileged organ (Dufour et al., 2005). Leydig cells start to differentiate in the end of the proliferative phase of Sertoli cells (Baker et al., 1999; Nef et al., 2000; O’Shaughnessy et al., 2008) and form the stable cell line indispensable for the production of male sex hormones.

The origin of individual testicular somatic cell lineages in mouse is still controversial. Precursors of Sertoli cells were detected in the population of coelomic epithelial cells migrated into the gonad 11.5 days post-coitum (Karl and Capel, 1998). Later publications disproved these findings and showed that pre-Sertoli cells are already present in the developing gonad together with arrived germ cells and form Sertoli germ cell mass (SGCM) (reviewed in Cool et al., 2012). Based on the expression of the low affinity neurotrophin receptor p75, peritubular myoid cells were found as mesenchymal precursors migrated from an adjacent mesonephric tissue (Campagnolo et al., 2001); however, this result was also disproved and only endothelial cells, but not PTMCs, were identified as a migrating population from mesonephros to the gonadal base (Combes et al., 2009). Authors performed *ex vivo* assay in which they co-cultured a wild-type male genital ridge alongside mesonephroi constitutively expressing GFP (Nishino et al., 2000). They found that endothelial cells with VE-cadherin expression, and not p75 positive PTMCs, are the only migrating cells entering the gonad. Furthermore, endothelial cells were identified as being indispensable for establishing a proper seminiferous tubule architecture (Combes et al., 2009).

Regarding humans, Chikhovskaya et al. (2012) used frozen testicular biopsies for variable enzymatic digestions and subsequent cultivation *in vitro*. Over 30-50 days embryonic stem cell (ESC)-like colonies emerged. Gene expression analysis revealed a low level of pluripotency markers such as *POU5F1, NANOG* and *SOX2* which was in disagreement with similar studies performed on mouse where such colonies were found to be derived from dedifferentiated spermatogonial stem cells (SSCs) and showed the ability to form teratoma (Guan et al., 2006; Kanatsu-Shinohara et al., 2004, 2008; Ko et al., 2009). Human testicular cells expressed mesenchymal stem cell (MSC) markers and were able to differentiate to three mesodermal lineages (adipocytes, chondrocytes and osteocytes) indicating their multipotent but not pluripotent character (Chikhovskaya et al., 2014).
of evolutionary immunology due to the potential utilization of xenogeneic Sertoli cells for co-transplantation with grafts without the need of immunosuppressive treatment. In this regard, well-established non-mammalian vertebrate model organisms are desirable and the diploid amphibian *Xenopus tropicalis* suits these requirements well. *X. tropicalis* is highly valuable in the fields of early vertebrate development, cell biology, and genome evolution, and large oocytes, outer fecundation and embryonic development make it feasible for microinjection or transplantation experiments. The *X. tropicalis* genome is fully sequenced and arranged into linkage groups (Hellsten et al., 2010; Wells et al., 2011), compared to evolutionarily-close fish model organisms (zebrafish, carp, trout etc.) the genome is diploid (Tymowska, 1973) and thus more suitable for gene function studies (Geach and Zimmerman, 2011).

Here we present a successful establishment and *in vitro* and *in vivo* (allogeneic transplantation into the tadpole peritoneal cavity) characterization of a stable cell culture derived from mechanically disrupted testes of a juvenile *X. tropicalis* male three months after metamorphosis. The cell culture is composed of a proliferative testicular cell feeder layer [*X. tropicalis* testicular somatic cells (*XtTSC*)] and testicular cell colonies [*X. tropicalis* testicular somatic cell colonies (*XtTSCc*)]. Reverse transcription (RT) and quantitative polymerase chain reaction (qPCR) analysis revealed a strong expression of mesenchymal, Sertoli and peritubular myoid cell markers; however germ cell markers were not detected, which confirms their somatic origin. Double immunocytochemical staining against Sox9 (SC marker) and Sma (marker of PTMC) clearly showed the presence of both antigens in ~80% of cells. This result indicates that at least in *Xenopus* there exist a common progenitor of Sertoli cell and PTMC lineages emerging from mesenchymal cells present in developing testes.

**RESULTS**

**Morphological and gene expression characterization of *X. tropicalis* testicular cell culture**

After establishing a *X. tropicalis* testicular cell culture, the adherent cells formed a feeder layer (*XtTSC*) with the morphological characteristics of Pre-Sertoli cells (Fig. 1A). Long-term cultivation enables the forming of colonies (*XtTSCc*) resembling embryonic stem cells (ESC) (Fig. 1B). The ultrastructure and cell arrangement within the colony were visualized via transmission electron microscopy (TEM). Sertoli cell-like cells surrounded the colony in two or three tight layers (Fig. 1E), and few of them were found inside. TEM showed that *XtTSCs* and *XtTSCcs* were arranged individually in an extensive amount of extracellular matrix (Fig. 1F).

Reverse transcription polymerase chain reaction (RT-PCR) analysis revealed a similar gene expression profile for both cell

![Fig. 1. In vitro characterization of *X. tropicalis* cell culture.](http://bio.biologists.org/)
types. The feeder layer and colonies were positive for pluripotency markers klf4 (kruppel-like factor 4), c-myc and telomerase reverse transcriptase (tert). However, the key pluripotency genes POU5F1 (in X. tropicalis pou5f3.1, pou5f3.2 and pou5f3.3) (Morrison and Brickman, 2006; Frankenberger et al., 2014) or sox2 (sex determining region Y box 2) were downregulated, suggesting that our cells are not in a pluripotent state as has been defined in the mouse model. Unfortunately, expression of the nanog gene, another key player in pluripotency acquisition (Silva et al., 2009), could not be determined since no homologue has been described in Xenopus yet. Germ cell markers such as dazl, ddx4 and ddx25 were not detected, this result confirmed the somatic origin of testicular cells. More detailed characterization was based on expression markers encompassing Sertoli cells (sox9, kitlg, vim and lif), peritubular myoid cells (acta2 and lif), Leydig cells (cyp11a1 and cyp17a1) and markers of mesenchymal cells (itgb1 - cd29, cd44 and thy1 - cd90). Except for Leydig cell markers, both cell types were positive for all above mentioned genes (Fig. 2A).

RT-PCR data was confirmed by qPCR analysis. The standard deviation of the RNA spike quantification across all samples was 0.2 cycles, which shows evidence of minimal technical variation and high reproducibility. The hierarchical clustering was performed according to two groups of analyzed markers, germ cell markers and testis-associates markers. Each heatmap included an RNA spike as a highly stable transcript across the cell types and housekeeping gene odc1. The result of the clustering indicated that the gene expression profile of testicular tissue is different from XtTSC and XtTSCc groups. Transcripts dazl, ddx25 and ddx4 are exclusively expressed in the testes, whereas expression of lif is substantially reduced in comparison with XtTSCs and XtTSCcs (Fig. 2B). Immunocytochemistry on feeder cells and colonies employing Sox9, Sma (smooth muscle α-actin) and vimentin antibodies revealed their colocalization on more than 80% of cells (Fig. 3). Taken together, we concluded that X. tropicalis testicular cell culture represents a population of Sertoli cell and PTMC common progenitors. To test if these cells are also present in adult individuals we prepared agarose embedded sections of X. tropicalis and mouse testes. After double staining with Sox9 and Sma antibodies we found individual cells expressing both antigens in the interstitial space close to the seminiferous tubules in X. tropicalis and even in mouse testis (Fig. 4).

Sertoli cells produce many soluble factors necessary for germ cell survival and proliferation. One of them, the leukemia inhibitory...
factor (Lif), turned out to be crucial for in vitro enhanced XtTSC survival and colony forming activity. Although both the XtTSCs and XtTSCcs express their own lif (measured on the RNA level) (Fig. 2A), the addition of recombinant mouse LIF into the cultivation medium entailed a rapid formation and expansion of XtTSCc colonies. However, a total proliferation rate was unaffected by LIF since experimental groups (+LIF and −LIF) revealed the same growth curves as depicted on Fig. 1G.

In vivo migration potential of testicular somatic cells

A peritoneal cavity of tadpoles at stage 41 was used for the transplantation of transgenic XtTSCc-RFP and XtTSC-RFP expressing Katushka RFP under ubiquitous CAG promotor (Fig. 1C,D). Cell microinjection of 500 cells per peritoneum was performed through the dorsal side as depicted in (Fig. 5A). One week after transplantation we observed cell deposits mostly in heart and pronephros (Fig. 5B-E). During three following weeks transplanted cells strongly proliferated and formed a dense cell-to-cell connecting net growing through the tadpole’s body (Fig. 5F,G). Immunohistochemical analysis of agarose embedded sections of tadpoles 0, 1 and 30 days after transplantation revealed a strong vimentin and RFP colocalization (Fig. 5H). However, expression of Sox9 and Sma, found in testicular cells prior to microinjection was not detected even 2 h after transplantation when tadpoles from group ‘0 day’ were fixed. Interestingly, 30 days after microinjection we observed Sox9 expression in a few RFP-positive cells indicating their potential differentiation into Sertoli cells or chondrocytes where this protein is also considered a cell-specific marker. Since both cell types (XtTSCc-RFP and XtTSC-RFP) showed the same migration and expression pattern, here we published only data concerning transplantation of testicular somatic cell colonies (XtTSCc).

DISCUSSION

In this study we characterized a newly established X. tropicalis testicular cell culture encompassing adherent feeder Sertoli-like cells (XtTSC) and cell colonies resembling ESC (XtTSCc). A long-term stem cell culture derived from testis was firstly described by Kanatsu-Shinohara et al. (2003) in mouse. Testes from newborn males were enzymatically dispersed and transferred to gelatine-coated plates. Here, in the presence of the glial cell line-derived neurotrophic factor (GDNF), epidermal growth factor (EGF), fibroblast growth factor 2 (FGF2) and leukemia inhibitory factor (LIF) spermatogonia could be propagated as cell clumps. One year later the same team announced a conversion of germ cells (GS) to multipotent germ stem cells (mGSs) using standard ESC cultivation medium containing 15% fetal bovine serum (FBS) and LIF (Kanatsu-Shinohara et al., 2004). In humans, the establishing of similar cell lines was found as a controversial. Four papers described the existence of ES-like cell colonies derived from testicular tissue (Conrad et al., 2008; Golestaneh et al., 2009; Kossack et al., 2009; Mizrak et al., 2010); however, in three of them (Golestaneh et al., 2009; Kossack et al., 2009; Mizrak et al., 2010) authors failed to induce teratoma after subcutaneous transplantation of testicular stem cells into immunodeficient mice. Chikhouskaya et al. (2012) revised previously published data of Mizrak et al. (2010) and performed an expanded study on human testis embryonic stem cell-like cells (htES-like cells) derived from frozen testicular samples using different enzyme digestion and cultivation conditions. Gene expression analysis revealed an expression of KLF4 and MYC but not SOX2, NANOG or key pluripotency marker POU5FI indicating their multipotent rather than pluripotent character. RT-PCR confirmed the presence of CD73, CD90 and CD150 and absence of CD31, CD34 and CD45 surface markers characteristic for the expression profile of mesenchymal stem cells. Repeated efforts to induce teratoma with htES-like cells in immunodeficient mouse failed. Chikhouskaya et al. (2014) differentiated htES-like cells in vitro into three mesodermal cell lineages typical for mesenchymal
stem cells (adipocytes, chondrocytes and osteocytes). In this study, up to five days after the mechanical disruption of X. tropicalis testis in the culture medium, adherent cells migrating from the organ were observed. Two months later small colonies of ES-like cells (XtTSCc) started to appear on the feeder layer (XtTSC). RT-PCR analysis showed the same expression profile as in the case of htES-like cells (Chikhovskaya et al., 2012). We detected only some pluripotency markers (klf4 and myc) and markers of mesenchymal cell differentiation (sox9, sma and vimentin) in the transplanted tadpoles. Immunohistochemistry of agarose-embedded sections of transplanted tadpoles using antibodies against Sox9, Sma and vimentin (green) and Katushka RFP (red) 0, 1 and 30 days after transplantation. RFP-positive cells were stained with vimentin antibody but not Sox9 or Sma even 2 h after transplantation. 30 days after microinjection, few cells start to express Sox9 indicating potential redifferentiation into Sertoli cells or chondrocytes where Sox9 is considered as a specific marker. The first three figures in each line were taken under fluorescence microscopy. The figures on the right side were taken under fluorescence stereomicroscopy. Nuclei were counterstained with DAPI (blue). Scale bars B-G, H (0 and 1 day after transplantation), 300 μm; scale bars in H (30 days after transplantation, staining with Sox9 and Sma antibodies), 900 μm; scale bars in H (30 days after transplantation, staining with vimentin antibody), 200 μm.
stem cells cd29 (itgb1), cd44 and cd90 (thy1). Germ cell markers (daz1, ddx4 and ddx25) were downregulated which further confirms the somatic rather than germ line origin of our testicular cells. Unlike Chikhovskaya et al. (2012) we performed gene expression analysis regarding testicular somatic lineages: Sertoli cells, peritubular myoid cells and Leydig cells. Except for the Leydig cell markers (cyp11a1 and cyp17a1) we found positive reactions for both remaining cell types (sox9, kitlg, lif, acta2 and vim). Immunocytochemistry revealed a colocalization of nuclear Sox9 and cytoplasmic Smα antigens. Together with previously published expression data in humans, we concluded that in X. tropicalis there exists a common progenitor of Sertoli and PTM cell lineages with morphological and expression characteristics of mesenchymal stem cells. Stem cell precursors for Leydig cells were already identified and characterized in interstitial space of rat testis close to seminiferous tubules (Inoue et al., 2016; Shan and Hardy, 1992; Stanley et al., 2011). We observed the same localization of cells double stained with Sox9 and Smα antibodies in X. tropicalis agarose embedded testicular sections and even in mouse samples.

The growth curve of our amphibian testicular cells showed a strong correlation between the addition of mouse leukemia inhibitory factor (mLIF) to the cultivation medium and cell colony forming activity. RT-PCR analysis revealed a relatively high lif transcription in both cell types (XiTSC and XiTSCc). In tests, a LIF production was determined in PTM cells located between the seminiferous tubules and the interstitium (Piquet-Pellorce et al., 2000) and also in remaining somatic cell types (Sertoli and Leydig cells) and spermatogonia (Jenab and Morris, 1998). LIF has an effect on spermatogonia proliferation and on the increased survival rate of Sertoli cells (De Miguel et al., 1996). We observed that for a successful establishment of amphibian testicular cell culture and its colony-forming activity, at least the initial addition of mLIF to the cultivation medium is indispensable. Further supplementation is important for the colony forming activity, but not for the testicular cell proliferation and survival. It is possible that initial addition of mouse LIF triggers the production of Xenopus homolog by testicular cells which is sufficient for their maintenance in the cell culture, but not for the formation of cell colonies.

The conservation of mammalian and non-mammalian Lif amino acid sequences is rather low (20-40%); however, all orthologous proteins share a conserved three-dimensional structure (Mathieu et al., 2012). As for lower vertebrates, lif CDNA was cloned in zebrafish, carp and goldfish (Fujiki et al., 2003; Abe et al., 2007; Hanington and Belosevic, 2007). Morpholino-based knockdown of lif in zebrafish revealed no obvious effect on early embryonic development. However, when its receptor (LIFR) had been targeted, effects on proper neural development were observed (Hanington et al., 2008). In chicken, LIF has been shown to function as an anti-differentiation factor for blastoderm cells (Horiiuchi et al., 2006). In amphibians, its effect on early embryonic development is still unknown.

Unlike testicular cell culture, RT-PCR and qPCR analysis showed a low expression of lif in adult testes. As mentioned above, in mouse, LIF is mostly produced by peritubular cells located on a periphery of seminiferous tubules (Piquet-Pellorce et al., 2000). It is possible, that in Xenopus testis Lif is expressed by scarce cells positively stained for Sox9 and Smα antigens. When transferred out of the testicular niche, these cells can proliferate in vitro and produce a higher amount of Lif.

El Jamil et al. (2008) studied the distribution of sox9 mRNA and protein in X. tropicalis testicular and ovarian cyrosections. In males, authors observed a Sox9 expression in nuclei of supporting (pre-Sertoli) cells located on the base of seminiferous tubules in the vicinity of germ cells. Unlike higher vertebrates, Sox9 is also expressed in oocyte cytoplasm indicating its role in the testicular differentiation but not in the sex determination.

To study of migration potential of X. tropicalis testicular somatic cells we performed a series of transplantation experiments with transgenic cell culture expressing Katushika RFP (XiTSCc-RFP). Cells were microinjected into the peritoneal cavity of tadpoles at stage 41. During the first week after microinjection we observed migration of RFP-positive cells into heart, pronephros (tadpole kidney) and intestine. The same organs are also major migratory targets for mouse mesenchymal stem cells intravenously injected into the bloodstream (reviewed in Cornelissen et al., 2015). Strong expression of vimentin in transplanted cells observed even one month after microinjection is typical for migratory mesenchymal cells (reviewed in Kim et al., 2014). In addition, differentiation markers of Sertoli and PTM cells (sox9 and Smα) were downregulated indicating a dedifferentiation process towards mesenchymal stem cells able to successfully proliferate and migrate through the tadpole body.

**MATERIALS AND METHODS**

**Ethical statement**

This study was carried out in strict accordance with the Act No. 246/1992 Coll., on the protection of animals against cruelty. An official permission was issued to the Faculty of Science, Charles University in Prague by the Ministry of Education, Youth and Sports of the Czech Republic (No. MSMT-37376/2014-4, date of expiry 3. 3. 2019).

**X. tropicalis testicular somatic cell culture**

The X. tropicalis testicular somatic cell culture was established from testes of juvenile male (Ivory Coast strain) 6 months after metamorphosis. For wash steps, diluted PBS (2:1 PBS/deionized H2O) was used due to different cell osmolarity of amphibian contrary to mammalian cells. Testes were extensively washed with diluted PBS and disrupted with needles in cultivation medium consisting of 33.3% L-15 and 33.3% RPMI 1640 HEPES modification medium (both Sigma-Aldrich) supplemented with 10% FBS (Life Technologies), 1.33 mg/ml sodium bicarbonate, 2 mM L-glutamine and 50 µg/ml gentamicin (all Sigma-Aldrich). Testicular explants were cultivated at 29.5°C with 5.5% CO2 for 5 days without any interference. Preparation of primary culture was successfully repeated three times with different X. tropicalis individuals originated from various breedings. All three lines exhibited the same morphology and behaviour during long-term cultivation and subsequent experiments.

For XiTSCc cultivation, medium has been improved with 1 mM sodium pyruvate, 0.1 mM 2-mercaptoethanol (both Sigma-Aldrich) and 1000 U/ml recombinant mouse LIF (ESGRO; Millipore) according to Chowdhury et al. (2010). The XiTSCc medium was changed every three days and cells were passaged every two weeks. To obtain a single cell suspension of XiTSCc, dissociation by a papain solution (61.25 mg/l papain, 0.5 mM EDTA and 1 mM L-cysteine in PBS without Ca2+, Mg2+; Biochrom AG) was efficient. Disintegration of colonies using Accutase® (Thermo Electron Corporation), Biotase (Biochrome AG) or trypsin-EDTA (0.5% trypsin-0.2% EDTA) was always incomplete. To measure growth, viable cells were seeded at a density of 1×104 cells per flask (75 cm²) and cultured in XiTSCc medium with and without recombinant mouse Lif for 45 days. During this time period cells were counted three times (15 days interval). Mean values were used to plot a growth curve for both cell types together and for XiTSCc separately.

**Visualization of XiTSCc via transmission electron microscopy (TEM)**

XiTSCc was separated from XiTSCc feeder layer by trypsin-EDTA treatment and filtered through a 20 µm filter (CellTrics®, Partec). For TEM, colonies were fixed, dehydrated in a graded ethanol series and acetone, and...
embedded in Araldite 502/PolyBed 812 resin (Polyscience, Inc.) as previously described (Hylili et al., 2007). Ultrathin sections (70 µm) were stained with uranyl acetate and lead citrate and examined with the JEOL 1011 transmission electron microscope with a Veleta CCD camera and Olympus Soft Imaging Solution GmbH software.

Preparation of transgenic Katushka RFP testicular cell culture
Testicular cells were electroporoized with 6 µg of ISpBSiSK-CAG-Katushka RFP vector (Shcherbo et al., 2007) using Nucleofector™ 2b Device (Lonza), program T-020 and nuleofection solution (5 mM KCl, 15 mM MgCl₂, 50 mM Na₂HPO₄, 100 mM NaCl). One month after nuleofection, transfected cells were separated on the basis of Katushka RFP signal by a fluorescence-activated cell sorting (FACS) using the inFlux v7 Sorter (BD Bioscience) (Fig. 1H).

RT-PCR and qRT-PCR
Total RNA was isolated from the adult X. tropicalis testes, XiTSC, XiTSCc, XiTSC-RFP and XiTSC-RFP using RNeasy Mini Kit (Qiagen) according to the manufacturer’s instructions. Reverse transcription was performed with the same amount of total RNA (200 ng) by the RevertAid H Minus First Strand DNA Synthesis Kit (Thermo Scientific). The relative expression of target genes was determined by using odc1 as a reference gene. Quantitative RT-PCR (qRT-PCR) was performed with a real-time CFX384 cycler system (BioRad) using iQTM SYBR® Green Supermix (BioRad). A RNA spike (TATAA Biocenter) was used to validate the signal by a fluorescence-activated cell sorting (FACS) using the inFlux v7 Sorter (BD Bioscience) (Fig. 1H).

Immunohistochemistry of vibratome sections from transplanted tadpoles
Transplanted tadpoles at stage 41 (day 0), 45 (day 1) and 55 (day 30) were fixed overnight in MEMFA (0.1 M MOPS, 2 mM EGTA, 1 mM MgSO₄, 150 mM NaCl, 40 mM NaH₂PO₄, 0.1% NaN₃) and the distribution of RFP positive cells was observed under a fluorescence stereomicroscope (Olympus).
