Th-Cre neurons results in reduced fR, hypoxic challenge (10% O2/90% N2), we saw reduced fR, CA neurons. Nonetheless, this work identifies a key respiratory expression domains of the stability during hypoxia. However, given the expanded non-CA hypercapnic and hypoxic ventilatory responses and breathing Th-Cre demonstrate the necessity of in addition to instability in both interbreath interval and tidal volume, resulting in a Cheyne-Stokes-like respiratory pattern. These findings demonstrate the necessity of Th-Cre-defined neurons for the hypercapnic and hypoxic ventilatory responses and breathing stability during hypoxia. However, given the expanded non-CA expression domains of the Tg(Th-Cre)FI172Gsat mouse line found in the brainstem, full phenotypic effect cannot be assigned solely to CA neurons. Nonetheless, this work identifies a key respiratory population that may lead to further insights into the circuitry that maintains respiratory stability in the face of homeostatic challenges.

INTRODUCTION
The catecholaminergic (CA) system, including the dopaminergic, noradrenergic and adrenergic systems, has been implicated in respiratory homeostasis (Li et al., 2008; Viemari, 2008). A better understanding of the role of the CA system in breathing is of importance for determining the potential mechanisms in developmental disorders with respiratory features, such as Congenital Central Hypoventilation Syndrome (CCHS) (Ramanantsoa and Gallego, 2013), Rett Syndrome (Katz et al., 2009; Weese-Mayer et al., 2006; Julu et al., 2001) and Sudden Infant Death Syndrome (SIDS) (Weese-Mayer et al., 2007); pathophysiologies such as obstructive sleep apnea (Hakim et al., 2012; Zhu et al., 2007), Acute Respiratory Distress Syndrome (ARDS) (Beiter et al., 2016) and Chronic Obstructive Pulmonary Disorder (COPD) (Williams et al., 2014; Yamauchi et al., 2012), where pulmonary dysfunction leads to hypoxia and respiratory destabilization; as well as to inform upon opiate-mediated respiratory arrest (Lalley, 2008). CA neurons are defined by their expression of tyrosine hydroxylase (Th), an early synthesizing enzyme in the CA pathway, leading to production of dopamine, noradrenaline and adrenaline, encompassing several populations in the nervous system. Here, we aimed to characterize the CA system in respiratory function in adult mice through the use of acute and targeted pharmacogenetic neuronal inhibition.

DREADD-mediated neuronal manipulations combined with recombinase based targeting strategies have provided an approach for functional circuit mapping that enables acute noninvasive perturbation of targeted populations while measuring respiratory output in conscious and unrestrained adult mice (Hennessy et al., 2017; Brust et al., 2014; Ray et al., 2012, 2011). The inhibitory pharmacogenetic DREADD or hM4Di receptor is inactive until activated by administration of the biologically inert ligand clozapine-N-oxide (CNO), to perturb neuron firing. To examine the potential aspects of respiratory physiology served by the CA system, we utilized the Cre-responsive RC::PDi mouse in combination with the B6.FVB(Cg)-Tg(Th-Cre)FI172Gsat (hereafter Th-Cre) driver to express the hM4D receptor in CA and other neurons defined by this frequently used Th-Cre driver. Using whole-body plethysmography, we assessed respiratory and metabolic function under baseline (21% O2/79% N2), hypercapnic (5% CO2/21% O2/74% N2), hypoxic (10% O2/90% N2), we saw reduced fR, V̇E and V̇O2. Under a hypoxic challenge (10% O2/90% N2), we saw reduced fR, V̇E and V̇O2, in addition to instability in both interbreath interval and tidal volume, resulting in a Cheyne-Stokes-like respiratory pattern. These findings demonstrate the necessity of Th-Cre-defined neurons for the hypercapnic and hypoxic ventilatory responses and breathing stability during hypoxia. However, given the expanded non-CA expression domains of the Tg(Th-Cre)FI172Gsat mouse line found in the brainstem, full phenotypic effect cannot be assigned solely to CA neurons. Nonetheless, this work identifies a key respiratory population that may lead to further insights into the circuitry that maintains respiratory stability in the face of homeostatic challenges.

INTRODUCTION
The catecholaminergic (CA) system, including the dopaminergic, noradrenergic and adrenergic systems, has been implicated in respiratory homeostasis (Li et al., 2008; Viemari, 2008). A better understanding of the role of the CA system in breathing is of importance for determining the potential mechanisms in developmental disorders with respiratory features, such as Congenital Central Hypoventilation Syndrome (CCHS) (Ramanantsoa and Gallego, 2013), Rett Syndrome (Katz et al., 2009; Weese-Mayer et al., 2006; Julu et al., 2001) and Sudden Infant Death Syndrome (SIDS) (Weese-Mayer et al., 2007); pathophysiologies such as obstructive sleep apnea (Hakim et al., 2012; Zhu et al., 2007), Acute Respiratory Distress Syndrome (ARDS) (Beiter et al., 2016) and Chronic Obstructive Pulmonary Disorder (COPD) (Williams et al., 2014; Yamauchi et al., 2012), where pulmonary dysfunction leads to hypoxia and respiratory destabilization; as well as to inform upon opiate-mediated respiratory arrest (Lalley, 2008). CA neurons are defined by their expression of tyrosine hydroxylase (Th), an early synthesizing enzyme in the CA pathway, leading to production of dopamine, noradrenaline and adrenaline, encompassing several populations in the nervous system. Here, we aimed to characterize the CA system in respiratory function in adult mice through the use of acute and targeted pharmacogenetic neuronal inhibition.

DREADD-mediated neuronal manipulations combined with recombinase based targeting strategies have provided an approach for functional circuit mapping that enables acute noninvasive perturbation of targeted populations while measuring respiratory output in conscious and unrestrained adult mice (Hennessy et al., 2017; Brust et al., 2014; Ray et al., 2012, 2011). The inhibitory pharmacogenetic DREADD or hM4Di receptor is inactive until activated by administration of the biologically inert ligand clozapine-N-oxide (CNO), to perturb neuron firing. To examine the potential aspects of respiratory physiology served by the CA system, we utilized the Cre-responsive RC::PDi mouse in combination with the B6.FVB(Cg)-Tg(Th-Cre)FI172Gsat (hereafter Th-Cre) driver to express the hM4D receptor in CA and other neurons defined by this frequently used Th-Cre driver. Using whole-body plethysmography, we assessed respiratory and metabolic function under baseline (21% O2/79% N2), hypercapnic (5% CO2/21% O2/74% N2), hypoxic (10% O2/90% N2) conditions after CNO-

RESULTS
The B6.FVB(Cg)-Tg(Th-Cre)FI172Gsat driver defines cells required for the hypercapnic ventilatory response
To assess the requirement of Th-Cre-defined neurons for the increased ventilatory response to hypercapnic (high CO2)
conditions, we employed the established RC::PDi inhibitory DREADD system and partnered it with the transgenic Th-Cre allele that captures CA neurons, in addition to several other brainstem populations, listed in Table 1. Using whole-body plethysmography, we measured the ventilatory response of animals under room air and 5% CO₂ before and after CNO administration (Fig. 1A). Th-Cre::PDi animals had baseline respiratory parameters similar to sibling controls during room air and 5% CO₂ conditions prior to CNO administration. In contrast, after CNO administration, Th-Cre::PDi mice showed significant respiratory and metabolic changes, especially under hypcapnic conditions (Fig. 2A,B). Under room air conditions, compared to pre-CNO values, we saw a statistically insignificant trend of increased $\bar{V}_E$ (Fig. 1D, +35.9%, $P=0.83$) mediated by small increases in both $f_R$ (Fig. 1B, +6.28%, $P=0.68$) and $V_T$ (Fig. 1C, +26.2%, $P=0.83$). However, overall $V_E/V_O_2$ was unchanged as $V_O_2$ increased (Fig. 1E, +27.9%, $P=0.1$). We also observed a reduction in periodic instability [Fig. 2F, −40.5% reduction in interbreath interval (IBI) coefficient of variation (CV), $P=0.017$]. Upon a post-CNO hypercapnic challenge, $\bar{V}_E$ was significantly reduced compared to pre-CNO values (Fig. 1D, −43.6%, $P=0.01$), mediated by a large reduction in $f_R$ (Fig. 1B, −26.3%, $P=0.001$) and a small but statistically insignificant reduction in $V_T$ (Fig. 1C, −22.7%, $P=0.12$). Overall $V_E/V_O_2$ (Fig. 1F, −69.9%, $P=0.001$) was also significantly reduced as post-CNO $V_O_2$ levels were similar to pre-CNO levels. Other than the decrease in periodic instability seen under room air conditions, Th-Cre::PDi animals did not show significant variability between pre- and post-CNO respiratory patterns under either room air conditions or the 5% CO₂ hypcapnic challenge (Fig. 2).

Sibling control PDi mice showed no significant differences before or after CNO administration in $V_E/V_O_2$, or constituent $f_R$, $V_T$, $V_E$, or $V_O_2$ parameters or waveform pattern under room air or hypcapnic challenge.

The B6.FVB(Cg)-Tg(Th-Cre)F1172Gsat driver defines cells required for the hypoxic ventilatory response

To assess the requirement of Th-Cre-defined neurons for the increased ventilatory response to hypoxic (low oxygen) conditions, we also measured respiration of Th-Cre::PDi animals under room air and 10% O₂ conditions (Fig. 3A). Mirroring the data from the hypcapnic challenge, Th-Cre::PDi mice showed a statistically insignificant trend of increased $V_E$ (Fig. 3D, +21.6%, $P=0.22$), mediated by small increases in $f_R$ (Fig. 3B, +5.1%, $P=0.57$) and $V_T$ (Fig. 3C, +14.0%, $P=0.15$), under room air after CNO administration as compared to pre-CNO values. Overall $V_E/V_O_2$ was unchanged once again as there was a parallel increase in $V_O_2$ (Fig. 3E, +26.6%, $P=0.22$). Compared to post-CNO sibling controls, Th-Cre::PDi mice showed a robustly reduced ventilatory hypoxic response (Fig. 3) with reductions in $f_R$ (Fig. 3B, −49.8%, $P<0.001$), $V_E$ (Fig. 3D, −46.3%, $P=0.0013$) and $V_O_2$ (Fig. 3E, −39.8%, $P<0.001$). The change in $V_E$ and $V_O_2$ was matched at 15 min as the $V_E/V_O_2$ ratio was not significantly different (Fig. 3F). Poincaré analysis at 15 min of 10% O₂ reveals significant respiratory instability (Fig. 4A,G,H) in the Th-Cre::PDi animals as compared to sibling controls in both interbreath interval (Fig. 4E, $P<0.001$ for CV comparison) and tidal volume (Fig. 4F, $P<0.001$), culminating in a significant increase in apneas (Fig. 4B, $P=0.01$), apnea length (Fig. 4C, $P<0.001$), and sighs (Fig. 4D, $P=0.01$).

Sibling control PDi mice showed no significant differences before or after CNO administration in $V_E/V_O_2$, or constituent $f_R$, $V_T$, $V_E$, or $V_O_2$, parameters or waveform pattern under room air.

The B6.FVB(Cg)-Tg(Th-Cre)F1172Gsat driver defines cells required for temperature maintenance

Temperature was taken as an element of the respiratory protocol at the beginning of the assay (pre-CNO at ambient temperature, ~23°C), immediately before CNO injection (pre-CNO at 30°C),

In addition to CA neurons, the Th-Cre driver also marks areas in the hypothalamus, amygdala and serotonergic nuclei. Cell populations targeted by the Th-Cre driver were identified in images of coronal sections provided by GENSAT. Structures and cell types were mapped by comparison to ‘The Mouse Brain in Stereotaxic Coordinates’ (3rd edition) (Franklin and Paxinos, 2008). GABA, gamma-aminobutyric acid; GnRH, gonadotropin-releasing hormone-expressing; GHRH, growth hormone-releasing hormone; AgRP, agouti-related peptide; NPY, neuropeptide Y.
immediately after the end of the assay (post-CNO at 30°C), and 30 min after the end of the assay (post-CNO at ambient temperature, ~23°C). In both the hypercapnic and hypoxic assays, Th-Cre; PDi animals showed a significant reduction in body temperature 30 min after the end of the assay as compared to sibling controls (Fig. 5, \( P=0.025 \) and \( P=0.001 \)). Additionally, they also showed a reduced temperature immediately after hypoxic exposure (\( P<0.001 \)).
system (CNS) beyond CA neurons, including subsets of the serotonergic raphé nuclei, the vestibular nucleus, and the reticulo- and pedunculo-tegmental nuclei of the pons (Table 1). Our data using the same hM4D-CNO system in combination with a dopaminergic-specific Dopamine-active-transporter (DAT)-Cre, a gene knock in with high fidelity, and a noradrenergic/adrenergic-specific Dopamine-beta-hydroxylase (DBH)-Cre, also show deficits in the hypercapnic response but do not phenocopy the hypoxic deficit and instability (data not shown), suggesting that distinct aspects of the phenotype seen in Th-Cre; PDi animals may arise from a non-CA population of cells.

Given the large number of anatomically defined populations captured in the CNS as well as possible peripheral populations, it becomes difficult to speculate on which populations may contribute to which aspects of the observed hypercapnic and hypoxic phenotypes. Further confounds arise from differences in approach. While we use a cell autonomous acute pharmacogenetic perturbation, many approaches utilize genetic, pharmacological and electrolytic lesions that may produce cell nonautonomous effects, induce developmental compensatory mechanisms, and capture fibers of passage and other intercalated cell types. Lastly, our respiratory measurements are normalized to oxygen

**Fig. 2.** Th-Cre; PDi mice have minimal changes in waveform pattern after DREADD-mediated acute perturbation under room air and hypercapnic conditions. (B) Representative respiratory traces pre- and post-CNO during hypercapnic breathing conditions in Th-Cre; PDi animals. (C-G) Th-Cre; PDi animals (n=12) showed a reduction in periodic instability (F) after CNO administration under baseline conditions (P<0.017) and no change in waveform parameters (apnea frequency, average apnea length, sigh frequency, periodic and volume instability) under hypercapnic conditions. Sibling controls (n=12) showed no significant difference before or after CNO administration. Individual data points and mean±s.e.m. are shown on each graph. Statistical significance was determined using a linear mixed-effects regression model with animal type (experimental or control) and CNO treatment (pre or post) as fixed effects and animal ID as a random effect. *P<0.05; **P<0.01; ***P<0.001; ns, not significant.
consumption, which can partially account for indirect or secondary respiratory changes that may result from increased or decreased metabolic drive. Nonetheless, it is likely that we are perturbing several neuron populations that are important to different aspects of breathing in developmental disorders, pathophysiologies and neurodegenerative disorders.

Several developmental disorders such as Rett Syndrome (Katz et al., 2009; Weese-Mayer et al., 2006; Viemari et al., 2005), Pit-

Hopkins Syndrome (Peippo and Ignatius, 2012) and CCHS (Ramanantsoa and Gallego, 2013) show respiratory instability and reduced chemosensory function. In these disorders, central serotonergic and noradrenergic chemosensory function has been shown to be affected and appear to be captured by this driver (Tuppy et al., 2015; Oliveira et al., 2017). Given that this model only shows respiratory instability under hypoxic challenges, the B6.FVB(Cg)-Tg(Th-Cre)F1172Gsat driver defines new populations that either as a whole or separately may play a role in the circuitry that is developmentally perturbed in these pathophysiologies, or engaged when responding to hypoxic stress from obstruction, compromised pulmonary function or neurodegeneration.

Finally, perturbation of Th-Cre; PDi-defined neurons resulted in significant temperature deficits 30 min after removal from the chamber (~70 min after CNO injection) and a deficit immediately after hypoxic exposure (~40 min after CNO injection). As thermogenesis is a crucial component of physiological homeostasis, this suggests that the Th-Cre driver captures cells critical for temperature maintenance and may play a role in metabolic homeostasis.

Conclusions

The results presented here define a set of neurons that encompass the CA system and other distinct populations in the brainstem that play a role in room air respiration and metabolic regulation, and are also required for the hypercapnic and hypoxic ventilatory reflexes, and respiratory stability while facing a homeostatic challenge. This work sets the stage for future studies to more closely model respiratory pathophysiologies to determine the critical subsets of neurons required for respiratory stability under hypoxic conditions, yielding key insights as to the neural substrates that underlie congenital and adult respiratory pathophysiologies.

MATERIALS AND METHODS

Mice

Studies were approved by the Baylor College of Medicine Institutional Animal Care and Use Committee (IACUC) under protocol AN-6171, and all experiments were performed in accordance with relevant guidelines and regulations.

Heterozygous B6.FVB(Cg)-Tg(Th-Cre)F1172Gsat (Th-Cre) mice were mated to homozygous RC::PDi mice to derive sibling cohorts in which all mice carried the RC::PDi allele. RC::PDi mice were maintained in the colony by backcrossing to C57BL/6J mice before homoyzogising. Sibling mice that did not inherit the Th-Cre allele were used as sibling controls to the Th-Cre::PDi offspring. All experimental animals were treated in compliance with the United States Department of Health and Human Services and the Baylor College of Medicine IACUC guidelines.

Whole-body plethysmography

Mouse respiration was measured in a custom built barometric whole-body plethysmograph. Ventilation was calibrated to a series of 2 µl pipetman injections into an empty 140 ml water-jacketed temperature-controlled chamber at a rate of 3 Hz, while measuring baseline gas composition for each assay. The rate of gas inflow and outflow was continuously controlled via dual rotameters. Flow rate was 198.11 ml/min. Gas was humidified to 100% by passing through a water column prior to entering the chamber and dehumidified by passing through 20 cm Nafion tubing encased in silica desiccant. Plethysmography pressure changes were measured using a DP45 differential pressure transducer and CD15 carrier demodulator (Validyne, Northridge, USA) in comparison to a reference chamber and recorded with LabChartPro (ADInstruments, Colorado Springs, USA) in real time. Chamber temperature was constantly monitored using a MicroThermo 2 and probe (ThermoWorks, American Fork, USA), and was recorded with LabChartPro in real time. Subsequent waveforms were analyzed offline to determine respiratory rate (f_R), tidal volume (V_T), minute ventilation (V_E), oxygen consumption (V_O2) and minute ventilation normalized to oxygen consumption (V_E/V_O2).

Experimental design

Hypercapnic assay

Twelve Th-Cre; PDi mice and 12 sibling control mice were assayed for their respiratory response in room air (21% O2/79% N2) and in 5% CO2 balanced...
with room air before and after CNO administration (Fig. 1A). Ten male and two female Th-Cre; Pdi mice, and seven male and five female sibling controls, from nine litters were assayed. The animals ranged in age from 3 months to 6 months, and body weight ranged from 19.7 g to 45.2 g. For each animal, the weight and rectal temperature was taken before the animal was placed in the plethysmography chamber (held at ∼31-32°C). After acclimation (typically 20-40 min, indicated by a steady respiratory trace free from movement artifact), a 20-min baseline room air trace was taken, followed by a 20-min exposure to 5% CO2, followed by another 20 min of room air to return respiratory parameters to baseline. The animal was then taken out of the chamber for another rectal temperature measurement and intraperitoneal injection of CNO dissolved in saline at 1 mg/ml for an effective concentration of 10 mg/kg. Prior studies suggest that behavioral changes from CNO in transgenic mice expressing DREADDs can take effect within 5-15 min of injection (Alexander et al., 2009; Ray et al., 2011), and clears from plasma within 2 h (Guettier et al., 2009), although effects within 5-15 min of injection (Alexander et al., 2009; Ray et al., 2011), and a final 20 min of room air before an end temperature was taken. Temperature was taken again 30 min after the end of the assay after the mouse was singly housed at ambient temperature (∼23°C).

Hypoxic assay

Eleven Th-Cre; Pdi mice and 10 sibling control mice were assayed for their respiratory response in room air both before and after CNO administration, and in post-CNO 10% O2. Nine male and two female Th-Cre; Pdi mice, and six male and four female sibling controls, from eight litters were assayed. The animals ranged in age from 4.5 months to 7 months, and body weight ranged from 24.7 g to 50.1 g. The protocol was similar to the hypercapnic assay, but instead of a 5% CO2 exposure, the animal was exposed to 10% O2 balanced with N2 20 min after CNO administration (Fig. 3A). Animals were not exposed to a pre-CNO 10% O2 condition to avoid potential confounds of hypoxic plasticity.

Data analysis

Respiratory waveforms were collected when the mouse was at rest, and readings were free from movement artifacts. A minimum of 1 min cumulative data collected from traces at least 5 s long from the last 5 min of a given experimental condition were analyzed. No filtering or smoothing was applied to the pressure waveform. Tidal volume (VT) was determined as described (Ray et al., 2011). Oxygen consumption was determined by comparing the gas composition between calibration in an empty chamber and live breathing using an AEI oxygen sensor and analyzer (AEI Technologies, Pittsburgh, USA).

Poincaré plots and apnea and sigh measurements were determined using at least 1 min of movement-free traces from each breathing condition. Apneas were defined as an IBI that was more than twice as long as the average IBI. Sighs were defined as a breath that had more than twice the amplitude of the average breath. The CV of the IBI and amplitude were also calculated from the same trace compilation of each breathing condition (standard error IBI or amplitude/mean IBI or amplitude) and defined as the periodic and volume instabilities, respectively.

Statistics

Room air and hypercapnic results were compared using a linear mixed-effects regression model with an animal type (experimental or control) and CNO treatment (pre or post) as fixed effects and animal ID as a random effect. Hypoxic and temperature results were compared between animal types using a linear mixed-effects regression model with animal type as a fixed effect. Individual data points and mean±s.e.m. are shown on each graph in all figures.

CNS Cre activity pattern

Cell populations targeted by the Tg(Th-Cre)FI172Gsat driver were identified in images of coronal sections provided by the Gene Expression Nervous System Atlas (GENSAT). Structures and cell types were mapped by comparison to Franklin and Paxinos (2008).

Acknowledgements

We thank Ronda Kram for technical assistance with mouse husbandry and maintenance.
